Capacitation of mouse spermatozoa

II. Protein tyrosine phosphorylation and capacitation are regulated by a cAMP-dependent pathway

In the accompanying report (Visconti, P.E., Bailey, J.L., Moore, G.D., Pan, D., Olds-Clarke, P. and Kopf, G.S. (1995) Development, 121, 1129-1137) we demonstrated that the tyrosine phosphorylation of a subset of mouse sperm proteins of Mr 40,000-120,000 was correlated with the capacitation state of the sperm. The mechanism by which protein tyrosine phosphorylation is regulated in sperm during this process is the subject of this report. Cauda epididymal sperm, when incubated in media devoid of NaHCO₃, CaCl₂ or bovine serum albumin do not display the capacitation-associated increases in protein tyrosine phosphorylation of this subset of proteins. This NaHCO₃, CaCl₂ or bovine serum albumin requirement for protein tyrosine phosphorylation can be completely overcome by the addition of biologically active, but not inactive, cAMP analogues. Addition of the active cAMP analogues to sperm incubated in media devoid of NaHCO₃, CaCl₂ or bovine serum albumin overcomes the inability of these media to support capacitation, as assessed by the ability of the cells to acquire the pattern B chlortetracycline fluorescence, to undergo the zona pellucida-induced acrosome reaction and, in some cases, to fertilize metaphase II-arrested eggs in vitro. The effects of the cAMP analogues to enhance protein tyrosine phosphorylation and to promote capacitation appear to be at the level of the cAMP-dependent protein kinase (PKA), since two specific inhibitors of this enzyme (H-89 and Rp-cAMPS) block the capacitation-dependent increases in protein tyrosine phosphorylation in sperm incubated in media supporting capacitation. Capacitation, as assessed by the aforementioned endpoints, also appears to be inhibited by H-89 in a concentration-dependent manner. These results provide further evidence for the interrelationship between protein tyrosine phosphorylation and the appearance of the capacitated state in mouse sperm. They also demonstrate that both protein tyrosine phosphorylation and capacitation appear to be regulated by cAMP/PKA. Up-regulation of protein tyrosine phosphorylation and capacitation appear to be regulated by cAMP/PKA. Up-regulation of protein tyrosine phosphorylation by cAMP/PKA in sperm is, to our knowledge, the first demonstration of such an interrelationship between tyrosine kinase/phosphatase and PKA signaling pathways.

Key words: mouse, sperm, capacitation, fertilization, in vitro fertilization, tyrosine phosphorylation, cyclic AMP, protein kinase A
the preprogrammed cellular events that are ultimately necessary for the development of the capacitated state.

We have shown in the preceding report that the acquisition of the capacitated state in caudal epididymal mouse sperm, as assessed by the ability of the cells to acquire the pattern B chlortetracycline fluorescence, to undergo the ZP-induced acrosome reaction, and to fertilize metaphase II-arrested eggs in vitro, is accompanied by the protein tyrosine phosphorylation of a specific subset of sperm proteins (Visconti et al., 1995). The onset of both capacitation and the protein tyrosine phosphorylations are dependent on the presence of serum albumin, Ca\(^{2+}\) and NaHCO\(_3\) in the culture medium, three components that have been demonstrated to be essential for in vitro capacitation of sperm from a variety of different mammals (Yanagimachi, 1994 and references therein). Caput epididymal sperm, which do not possess the ability to undergo capacitation, do not display the protein tyrosine phosphorylations of this subset of proteins. We believe that protein tyrosine phosphorylation may represent an important pathway that may ultimately regulate events associated with capacitation.

The mechanism by which these protein tyrosine phosphorylations are regulated is the subject of this study. Of potential relevance to the requirement of extracellular Ca\(^{2+}\) and NaHCO\(_3\) for these protein tyrosine phosphorylations is the observation that these particular ions have been demonstrated to be involved in the regulation of mammalian sperm cAMP metabolism, and that changes in the concentration of this intracellular second messenger have been linked to both capacitation and the acrosome reaction. For example, it is known that Ca\(^{2+}\)-dependent elevations of guinea pig sperm cAMP concentrations are dependent on the presence of extracellular NaHCO\(_3\) and that the effects of NaHCO\(_3\) on this process do not appear related to changes in intracellular pH (Garbers et al., 1982). The effects of this cation and anion may be at the level of the adenyl cyclase, since the mammalian sperm enzyme has been demonstrated to be regulated directly/indirectly by Ca\(^{2+}\) (Hyne and Garbers, 1979), calmodulin (Gross et al., 1987), and NaHCO\(_3\) (Garty and Salomon, 1987; Okamura et al., 1988; Visconti et al., 1990). Ca\(^{2+}\) and NaHCO\(_3\) also appear to be required for capacitation (Fraser, 1987; Neill and Olds-Clarke, 1987; Boatman and Robbins, 1991) and the induction of the acrosome reaction (Hyne, 1984; Lee and Storey, 1986; Kopf and Gerton, 1991 and references therein; Spira and Breitbart, 1992). Moreover, changes in the activity of adenyl cyclase and cAMP have been postulated in some species to play a role in capacitation (Perreault and Rogers, 1982; Berger and Clegg, 1983; Boatman and Bavister, 1984; Stein and Fraser, 1984; Monks et al., 1986; Yanagimachi, 1994 and references therein).

The interrelationships between NaHCO\(_3\), Ca\(^{2+}\), cAMP, protein tyrosine phosphorylation and capacitation in cauda epididymal mouse sperm was further examined in the present report. The capacitation-associated changes in protein tyrosine phosphorylation that are dependent on the presence of bovine serum albumin (BSA), Ca\(^{2+}\) and HCO\(_3^-\) can be mimicked in the absence of each of these required media constituents by the addition of active, but not inactive, membrane-permeable cAMP analogues. Correlated with the stimulatory effects of these cAMP analogues on protein tyrosine phosphorylation is a stimulatory effect of these analogues on capacitation. The stimulatory effects of cAMP on protein tyrosine phosphorylation and capacitation appear to be at the level of PKA.

**MATERIALS AND METHODS**

**Reagents**

Sp-cAMPS, Rp-cAMPS, 8-bromo cAMP and KN-62 were from Research Biochemicals International (Natick, MA). H89 (N-[2-(p-bromocinnamylamino)ethyl]-5-isouquinolinesulfonamide), staurosporine and chelerythrine were from LC Labs (Woburn, MA). Dibutyryl cAMP and IBMX were purchased from Sigma. Anti-phosphotyrosine antibody (clone 4G10) was obtained from UBI (Lake Placid, NY). All other reagents were of the highest analytical grade.

**Culture media**

The basic medium used throughout these studies for the preparation of sperm was a modified Krebs Ringer bicarbonate medium (HMB-Hepes buffered), as described by Lee and Storey (1986). The preparation of the media is as described in the accompanying report (Visconti et al., 1995).

**Preparation of sperm and in vitro fertilization**

Uncapacitated caudal epididymal sperm were collected from CD1 retired breeder male mice by the methods described in the accompanying paper (Visconti et al., 1995). In vitro fertilization of metaphase II-arrested eggs was performed as previously described (Moore et al., 1993), with the modifications described in the accompanying report (Visconti et al., 1995).

**Preparation and solubilization of mouse zonae pellucidae**

Zonae pellucidae were prepared from homogenized oocytes of virgin female 22-day old outbred CD-1 mice (Charles River) as described in Ward et al. (1992) and solubilized for all experiments by the procedures outlined in the previous report (Visconti et al., 1995).

**Chlortetracycline assay**

This assay was used to assess both the capacitation state of the sperm and the percentage of acrosome reactions. The experimental design and use of these assays is described in Visconti et al. (1995).

**Preparation of sperm membranes and measurement of adenyl cyclase activity**

Caudal epididymal spermatozoa were recovered as described by Endo et al. (1987, 1988), and incubated at a concentration of 1×10⁸ cells/ml for 1 hour at 37°C in a humidified incubator with 5% CO\(_2\) in air in Hepes-buffered modified bicarbonate Krebs-Ringer medium (HMB) containing 20 mg/ml BSA. At the end of the incubation, the sperm cells were diluted twice in HMB+BSA and centrifuged for 20 minutes (150 g) at room temperature. The resultant pellet was resuspended in ice-cold homogenization buffer (50 mM Hepes, 1 mM EGTA, 10% DMSO, pH 7.5) and gently homogenized (10 strokes in a loose glass-teflon homogenizer) under conditions that have been shown to maintain the ZP-G protein coupling (Ward et al., 1992). The homogenate was subjected to a low speed centrifugation (1500 g, 4°C) to pellet the membranes. The particulate crude membrane fraction was resuspended in the same homogenization buffer, aliquoted and kept frozen (−70°C). The adenyl cyclase assays were performed on membrane preparations less than a week old. Generally, 250-350 µg of membrane proteins were obtained using 20 males.

Adenylyl cyclase activity was measured by the conversion of [α-32P]ATP to [32P]cAMP (Salomon et al., 1974). The assay was carried out for 20 minutes at 37°C in the presence of 50 mM Hepes, 1.5 mM ATP, 15 mM MgCl\(_2\), 10 mM KCl, 4 mM DTT, 1 mM IBMX, 16 µg creatine kinase, 3.2 mM creatine phosphate and 2.5-3 µCi [α-
2P|ATP, pH 7.6 in a final volume of 30 µl. The assay was started by the addition of 8 µl of membrane suspension containing 0.5-1.2 µg of protein, and was terminated by the addition of 25 µl of the termination buffer (36.4 mM ATP, 10 mM cAMP, 1% SDS, and 3000 cpm [3H]cAMP) followed by heating in a boiling water bath for 5 minutes.

The [3P|cAMP formed was purified following chromatography using Dowex and Alumina columns (Salomon et al., 1974) and the [3H]cAMP was used as an internal standard for the evaluation of recovery.

**SDS-PAGE and immunoblotting**

SDS-PAGE (Laemmli, 1970) was performed in 10% gels. Electrophoretic transfer of proteins to Immobilon P in all experiments was carried out according to the method of Towbin et al. (1979) at 30 V (constant) for 6 hours at 4°C. Immunodetection of proteins on Immobilon P was performed at room temperature as described previously (Kalab et al., 1994) using a monoclonal antibody against phosphotyrosine (clone 4G10) and enhanced chemiluminescence detection using an ECL kit (Amersham Corp.) according to the manufacturer’s instructions.

**Statistical methods**

Statistical comparison between the treatment groups was always performed against the control lacking the addition of the respective media constituent using a Student’s t-test. The acrosome reaction data were analyzed using a Student’s t-test by comparing the inducible component of the acrosome reaction [e.g., the ZP-induced acrosome reaction following subtraction of the spontaneous acrosome reaction (ARsp - AR spont.)].

**RESULTS**

**Effects of bicarbonate anion on mouse sperm adenylyl cyclase activity**

We first examined whether the mouse sperm adenylyl cyclase could be stimulated by HCO3\(^{-}\). Membranes from capacitated mouse sperm were prepared under conditions that support ZP3-Gi protein-coupled signal transduction (Ward et al., 1992) and assayed for adenylyl cyclase activity in the absence and presence of various concentrations of NaHCO3. As shown in Fig. 1, NaHCO3 stimulated adenylyl cyclase activity in a concentration-dependent manner that was maximal at 50 mM. These stimulatory effects compare favorably with those effects seen by Okamura et al. (1985), Garty and Salomon (1987) and Visconti et al. (1990). The effect of NaHCO3 on mouse sperm adenylyl cyclase activity is due to the effect of HCO3\(^{-}\), since substituting the NaHCO3 with NaCl had no effect on the activity of the enzyme (data not shown). Moreover, the effect of NaHCO3 on enzyme activity did not result as a consequence of changes in assay pH, since adjusting the pH of the buffers used in the enzyme assay from pH 7-8 had no effect on enzyme activity (data not shown).

**Cyclic AMP analogues can substitute for bicarbonate anion in supporting both protein tyrosine phosphorylation and capacitation**

As previously demonstrated, the presence of NaHCO3 in the medium is required for capacitation and the associated changes in protein tyrosine phosphorylation (Visconti et al., 1995, Figs 6, 7). Since NaHCO3 stimulated the mouse sperm adenylyl cyclase (Fig. 1), we determined whether the addition of membrane permeable cAMP analogues could substitute for NaHCO3 in promoting both protein tyrosine phosphorylation and capacitation. Caudal epididymal sperm were incubated for different periods of time in complete medium or in medium devoid of NaHCO3 in either the absence or presence of 1 mM dibutyryl cAMP (db-cA) plus 100 µM IBMX. When compared to sperm incubated in complete medium, sperm incubated in medium devoid of NaHCO3 did not display the capacitation-associated changes in protein tyrosine phosphorylation, even after incubation times up to 5 hours (Fig. 2A). However, when the NaHCO3-free culture medium was supplemented with 1 mM db-cA plus 100 µM IBMX, the protein tyrosine phosphorylation was observed and this was maximal by 3 hours of incubation (Fig. 2A). As described in the previous report (Visconti et al., 1995), the degree of tyrosine phosphorylation of the p95/116 hexokinase, which is the major phosphotyrosine-containing protein in mouse sperm membranes (Kalab et al., 1994), was not affected by the absence of NaHCO3 in the medium and its phosphorylation did not appear to be modulated by the addition of 1 mM db-cA plus 100 µM IBMX (Fig. 2A). These effects on protein tyrosine phosphorylation were not limited to db-cA since 1 mM dibutyryl cAMP (db-cA) plus 100 µM IBMX (Fig. 2A). These effects compare favorably with those effects seen by Okamura et al. (1985), Garty and Salomon (1987) and Visconti et al. (1990) using a monoclonal antibody against phosphotyrosine (clone 4G10) and enhanced chemiluminescence detection using an ECL kit (Amersham Corp.) according to the manufacturer’s instructions.

NaHCO3 in promoting both protein tyrosine phosphorylation and capacitation. Caudal epididymal sperm were incubated for different periods of time in complete medium or in medium devoid of NaHCO3 in either the absence or presence of 1 mM dibutyryl cAMP (db-cA) plus 100 µM IBMX. When compared to sperm incubated in complete medium, sperm incubated in medium devoid of NaHCO3 did not display the capacitation-associated changes in protein tyrosine phosphorylation, even after incubation times up to 5 hours (Fig. 2A). However, when the NaHCO3-free culture medium was supplemented with 1 mM db-cA plus 100 µM IBMX, the protein tyrosine phosphorylation was observed and this was maximal by 3 hours of incubation (Fig. 2A). As described in the previous report (Visconti et al., 1995), the degree of tyrosine phosphorylation of the p95/116 hexokinase, which is the major phosphotyrosine-containing protein in mouse sperm membranes (Kalab et al., 1994), was not affected by the absence of NaHCO3 in the medium and its phosphorylation did not appear to be modulated by the addition of 1 mM db-cA plus 100 µM IBMX (Fig. 2A). These effects on protein tyrosine phosphorylation were not limited to db-cA since 1 mM dibutyryl cAMP (db-cA) plus 100 µM IBMX (Fig. 2A). These effects compare favorably with those effects seen by Okamura et al. (1985), Garty and Salomon (1987) and Visconti et al. (1990) using a monoclonal antibody against phosphotyrosine (clone 4G10) and enhanced chemiluminescence detection using an ECL kit (Amersham Corp.) according to the manufacturer’s instructions.
hand panel). Such a differential effect was not observed when Sp-cA was used (Fig. 2B, compare left-hand and right-hand panels); this is probably due to its inability to be hydrolyzed by cyclic nucleotide phosphodiesterases. These effects appeared to be specific for cAMP analogues since dibutyryl cGMP, in either the absence or presence of IBMX, had no effect on protein tyrosine phosphorylation (data not shown).

Sperm incubated in medium devoid of NaHCO₃ also did not display the CTC fluorescence B pattern indicative of the capacitated state (Fig. 3A). The ZP-induced acrosome reaction was, cGMP, in either the absence or presence of IBMX, had no effect on protein tyrosine phosphorylation (data not shown).

Sperm incubated in medium devoid of NaHCO₃ also did not display the CTC fluorescence B pattern indicative of the capacitated state (Fig. 3A). The ZP-induced acrosome reaction was,
diesterases and phosphoprotein phosphatases (Kopf and
Since serum albumin is required for both capacitation (Yanag-
contain Ca2+/calmodulin activated cyclic nucleotide phospho-
phosphorylation and capacitation. Sperm incubated in medium devoid of added Ca2+ failed to display the capacitation-dependent changes in protein tyrosine phosphorylation (Fig. 4; Visconti et al., 1995). When sperm were incubated in Ca2+-free medium containing various cAMP analogues plus IBMX for a period of 90 minutes, the capacitation-dependent changes in protein tyrosine phosphorylation were observed when biologically active (Sp-cA; db-cA; 8Br-cA), but not inactive (Rp-cA), cAMP analogues were used (Fig. 4, right-hand panel). It is of interest that IBMX alone supported protein tyrosine phosphorylation, but not to the degree of that observed in the presence of the active cAMP analogues (Fig. 4, right-hand panel). This is due, presumably, to its function as an inhibitor of cyclic nucleotide phosphodiesterase activity. IBMX alone also supported a greater degree of protein tyrosine phosphorylation but Rp-cA appeared to inhibit the IBMX-induced changes in protein tyrosine phosphorylation. This is presumably due to the fact that Rp-cA, in addition to its ability to bind to the regulatory subunit of PKA but not activate the enzyme, has been demonstrated to function as a cAMP antagonist (Van Haastert et al., 1984; Parker Botelho et al., 1988) and might therefore abrogate the effects of IBMX as a cyclic nucleotide phosphodiesterase inhibitor by competing with endogenous cAMP. In contrast to the effects seen in the presence of IBMX, in the absence of this phosphodiesterase inhibitor only Sp-cA appeared to support the appearance of the capacitation-dependent changes in protein tyrosine phosphorylation (Fig. 4, left-hand panel). This is presumably due to the fact that this analogue is very effective in activating PKA and is very poorly hydrolyzed by cyclic nucleotide phosphodiesterases. These data suggest that cAMP analogues can substitute for Ca2+ deficiency in supporting protein tyrosine phosphorylation.

Sperm incubated in medium devoid of Ca2+, likewise, did not display the CTC fluorescence B pattern indicative of the capacitated state (Fig. 5A). The ZP-induced acrosome reaction was also completely dependent on the presence of Ca2+ in the medium (Fig. 5B). As was seen with protein tyrosine phosphorylation, the addition of 1 mM db-cA plus 100 µM IBMX to medium devoid of Ca2+ could substitute for Ca2+ in supporting the ability of the sperm to display the CTC fluorescence B pattern (Fig. 5A). In contrast, these agents did not support the ability of the sperm to undergo a ZP-induced acrosome reaction (Fig. 5B), presumably due to the fact that extracellular Ca2+ is essential for this exocytotic event (Yanagimachi, 1994).

Cyclic AMP analogues can substitute for serum albumin in supporting both protein tyrosine phosphorylation and capacitation

Since serum albumin is required for both capacitation (Yanagimachi, 1994 and references therein) and the appearance of the phosphotyrosine-containing proteins in caudal epididymal mouse sperm incubated in media devoid of CaCl2 (Visconti et al., 1995), we examined whether cAMP analogues could substitute for BSA in supporting both protein tyrosine phosphorylation and capacitation. Sperm incubated in medium devoid of added CaCl2 (Ca2+-free HMB) in either the absence (left-hand panel) or presence (right-hand panel) of 100 µM IBMX. These media were also supplemented with either no cAMP analogues (−) or with 1 mM Rp-cAMPS (Rp-cA), 1 mM Sp-cAMPS (Sp-cA), 1 mM dibutyryl cAMP (db-cA) or 0.5 mM 8 bromo-cAMP (8Br-cA). Sperm were also incubated in the presence of complete HMB (extreme right lane marked +Ca2+). This experiment was performed at least three times with similar results. Shown, is a representative experiment.

**Fig. 4.** Effects of cyclic AMP analogues and 3-isobutyl-1-methylxanthine (IBMX) on the appearance of phosphotyrosine-containing proteins in caudal epididymal mouse sperm incubated in medium devoid of CaCl2. Sperm were incubated for 90 minutes in HMB medium containing no added CaCl2 (Ca2+-free HMB) in either the absence (left-hand panel) or presence (right-hand panel) of 100 µM IBMX. Sperm were also incubated in the presence of complete HMB (extreme right lane marked +Ca2+). This experiment was performed at least three times with similar results. Shown, is a representative experiment.
Gerton, 1991; Tash et al., 1988) that may be more active in sperm incubated in the presence of Ca\(^{2+}\). In contrast to the effects seen in the presence of IBMX, in the absence of this phosphodiesterase inhibitor only Sp-cA appeared to support the appearance of the capacitation-dependent changes in protein tyrosine phosphorylation (Fig. 6, left-hand panel). These data suggest that cAMP analogues can substitute for BSA deficiency in supporting protein tyrosine phosphorylation.

Sperm incubated in medium devoid of BSA, likewise, did not display the CTC fluorescence B pattern indicative of the capacitated state (Fig. 7A). Capacitation was also not observed when polyvinyl alcohol (PVA) was substituted for BSA. It should be noted that protein tyrosine phosphorylation is also not supported when sperm are incubated in BSA-free medium supplemented with PVA (data not shown). The ZP-induced acrosome reaction was also completely dependent on the presence of BSA in the medium (Fig. 7B). The addition of 1 mM db-cA plus 100 \(\mu\)M IBMX, however, could substitute fully for BSA in supporting the ability of the sperm to display the CTC fluorescence B pattern (Fig. 7A) but not to undergo the ZP-induced acrosome reaction (Fig. 7B).

Although the effects of BSA depletion on capacitation using in vitro fertilization as an endpoint could not be assessed due to the fact that serum albumin is needed for the ZP-induced acrosome reaction (Fig. 7B), we did observe that sperm incubated under capacitation conditions in the absence of BSA but in the presence of 1 mM db-cA plus 100 \(\mu\)M IBMX, and then incubated with ZP-intact eggs in the presence of BSA, displayed a higher percentage fertilization (79%; 32 eggs assessed) than sperm incubated in capacitation medium devoid of both BSA and db-cA/100 \(\mu\)M IBMX (55%; 48 eggs assessed) (data not shown). These data are consistent with the notion that db-cA plus IBMX may function in the absence of BSA to accelerate the capacitation process and/or synchronize capacitation in a greater population of sperm (Fraser, 1981).

Gerton, 1991; Tash et al., 1988) that may be more active in sperm incubated in the presence of Ca\(^{2+}\). In contrast to the effects seen in the presence of IBMX, in the absence of this phosphodiesterase inhibitor only Sp-cA appeared to support the appearance of the capacitation-dependent changes in protein tyrosine phosphorylation (Fig. 6, left-hand panel). These data suggest that cAMP analogues can substitute for BSA deficiency in supporting protein tyrosine phosphorylation.

Sperm incubated in medium devoid of BSA, likewise, did not display the CTC fluorescence B pattern indicative of the capacitated state (Fig. 7A). Capacitation was also not observed when polyvinyl alcohol (PVA) was substituted for BSA. It should be noted that protein tyrosine phosphorylation is also not supported when sperm are incubated in BSA-free medium supplemented with PVA (data not shown). The ZP-induced acrosome reaction was also completely dependent on the presence of BSA in the medium (Fig. 7B). The addition of 1 mM db-cA plus 100 \(\mu\)M IBMX to the BSA-free medium, however, could substitute fully for BSA in supporting the ability of the sperm to display the CTC fluorescence B pattern (Fig. 7A) but not to undergo the ZP-induced acrosome reaction (Fig. 7B).

Although the effects of BSA depletion on capacitation using in vitro fertilization as an endpoint could not be assessed due to the fact that serum albumin is needed for the ZP-induced acrosome reaction (Fig. 7B), we did observe that sperm incubated under capacitation conditions in the absence of BSA but in the presence of 1 mM db-cA plus 100 \(\mu\)M IBMX, and then incubated with ZP-intact eggs in the presence of BSA, displayed a higher percentage fertilization (79%; 32 eggs assessed) than sperm incubated in capacitation medium devoid of both BSA and db-cA/100 \(\mu\)M IBMX (55%; 48 eggs assessed) (data not shown). These data are consistent with the notion that db-cA plus IBMX may function in the absence of BSA to accelerate the capacitation process and/or synchronize capacitation in a greater population of sperm (Fraser, 1981).
Protein tyrosine phosphorylation is accelerated by dibutyryl cAMP and IBMX in media that support capacitation

Since it has been demonstrated that dibutyrlyl cAMP accelerates capacitation in vitro in mouse sperm (Fraser, 1981), we examined whether the addition of db-cA plus IBMX influenced the time-dependent onset of protein tyrosine phosphorylation that occurs during the normal time course of capacitation in vitro. As shown in Fig. 8, when compared to controls, addition of 1 mM db-cA plus 100 µM IBMX to sperm in complete medium significantly reduced the time during which changes in protein tyrosine phosphorylation occurred.

Protein tyrosine phosphorylation and capacitation appear to be regulated by cAMP-dependent protein kinase

Since the primary intracellular target for cAMP action is the PKA, we examined whether PKA played a role in protein tyrosine phosphorylation and capacitation. Caudal epididymal sperm were incubated for 90 minutes in complete medium that supports capacitation in either the absence or presence of N-[2-(p-bromocinnamylamino)ethyl]-5-isooquinolinesulfonamide (H-89), a highly selective and cell permeable inhibitor of PKA (Chijiwa et al., 1990). As shown in Fig. 9A, H-89 inhibited protein tyrosine phosphorylation of sperm proteins in a concentration-dependent manner with maximal effects observed at 10 µM. In contrast, the tyrosine phosphorylation of the p95/116 hexokinase was unaffected by H-89 at all concentrations tested. In contrast to the effects of this PKA inhibitor on protein tyrosine phosphorylation, inhibitors of protein kinase C (1 µM staurosporine; 10 µM chelerythrine) and Ca²⁺/calmodulin-dependent protein kinase (10 µM KN-62) had no effects on protein tyrosine phosphorylation that accompanied capacitation (data not shown).

Sperm incubated in complete medium for 90 minutes did not display protein tyrosine phosphorylation when incubated with the cAMP antagonist Rp-cAMPS, whereas phosphorylation was observed in either the absence of a cAMP analogue or in the presence of the active cAMP analogue, Sp-cAMPS (Fig. 9B). The phosphorylation observed with Sp-cAMPS appeared to be higher than that observed in the absence of added cAMP analogue.

Fig. 7. Effects of dibutyrlyl cAMP plus 3-isobutyl-1-methylyxanthine (IBMX) on the percentage of caudal epididymal mouse sperm displaying chlortetracycline fluorescence pattern ‘B’ and the percentage of sperm undergoing the spontaneous and zona pellucida-induced acrosome reaction (chlortetracycline pattern ‘AR’) in medium containing bovine serum albumin, or in medium devoid of bovine serum albumin in either the absence or presence of polyvinyl alcohol. Sperm were incubated for a period of 90 minutes in BSA-free HMB, BSA-free HMB containing 1 mg/ml polyvinyl alcohol (PVA), HMB containing 3 mg/ml BSA, or in these media containing 1 mM dibutyrlycAMP (db-cA) plus 100 µM IBMX. (A) Sperm were assessed for the percentage of CTC pattern ‘B’, indicative of the capacitated state. Data represent the mean ± s.e.m., n=3. Sperm were incubated under conditions conducive to capacitation in complete medium (HMB) for the times indicated at the bottom of the figure in either the absence (No Additions) or presence of 1 mM db-cA plus 100 µM IBMX. This experiment was performed two times with similar results. Shown, is a representative experiment.
Statistical analysis was performed as described in Materials and Methods; * indicates the mean ± s.e.m., ** indicates the mean ± s.e.m. (solid bars).

Fig. 9. Effects of the protein kinase A inhibitor H-89, as well as Rp-cAMPS and Sp-cAMPS, on the appearance of phosphotyrosine-containing proteins in caudal epididymal mouse sperm incubated in complete media that support capacitation. (A) Sperm were incubated for 90 minutes in complete HMB medium in the absence or presence of increasing concentrations of H-89 and protein tyrosine phosphorylation measured. (B) Sperm were incubated for 90 minutes in complete HMB medium in the absence or presence of increasing concentrations of H-89 and protein tyrosine phosphorylation assessed. This experiment was performed at least three times with similar results. Shown, is a representative experiment.

H-89 was also observed to inhibit capacitation, as assessed by a number of criteria. The appearance of the CTC B pattern fluorescence was inhibited by H-89 in a concentration-dependent manner (Fig. 10A). This was accompanied by a loss in the ability of the sperm to undergo a ZP-induced acrosome reaction (Fig. 10B). Moreover, if sperm were incubated under capacitating conditions in the presence of 30 µM H-89, a concentration that inhibits tyrosine phosphorylation, the appearance of the CTC B pattern of fluorescence and the ZP-induced acrosome reaction (Figs 9, 10), in vitro fertilization of ZP-intact eggs is inhibited, as evidenced by a significant reduction in the formation of a pronucleus in eggs inseminated with H-89-treated sperm (Fig. 11, H-89 in capacitation medium; H-89 in both capacitation and fertilization media). The effect on fertilization is especially pronounced when the H-89 concentration is held at 30 µM by keeping the inhibitor in both the capacitation and fertilization media. The reduction in the inhibitory effect on fertilization observed when the H-89 is present only in the capacitation medium is probably due to the dilution of the H-89 at the time of in vitro insemination (from 30 µM to 0.2 µM). The lowering of the H-89 concentration during the 2 h insemination period might permit capacitation to occur so that the sperm can bind to the ZP, undergo the acrosome reaction, penetrate and fertilize the egg. Consistent with this hypothesis is the fact that after dilution of the sperm to the same extent in an H89-free medium, the protein tyrosine phosphorylation increases steadily (data not shown). The inhibitory effects of H-89 on fertilization do not appear to be due to an inhibitory effect of H-89 on the egg itself, since insemination of ZP-free eggs in H-89-containing fertilization medium with sperm that have been capacitated in the absence of H-89 does not inhibit in vitro fertilization (data not shown).

DISCUSSION

The data outlined in this report further support the interrelationship between protein tyrosine phosphorylation and the capacitation state of mouse sperm, since modulation of capacitation by the addition of cAMP analogues also modulates protein tyrosine phosphorylation. Moreover, inhibition of protein tyrosine phosphorylation and capacitation by two inhibitors of PKA (Rp-cAMPS; H89) that act on this enzyme by totally different mechanisms further support the linkage between these two events and strengthen the argument that PKA is required for the regulation of these two processes. The
fact that biologically active cAMP analogues can overcome the deficiency in protein tyrosine phosphorylation and capacitation seen in media devoid of NaHCO3. Ca2+ or BSA suggests that this second messenger functions downstream from events stimulated by these media constituents. Although some cAMP analogues added alone could completely substitute for specific media components in supporting protein tyrosine phosphorylation, the effects of some of these analogues on protein tyrosine phosphorylation was augmented when the experiments were carried out in the presence of a cyclic nucleotide phosphodiesterase inhibitor such as IBMX (Figs 2, 4, 6). Such an effect is consistent with the idea that cAMP is up-regulating protein tyrosine phosphorylation and that inhibition of cAMP hydrolysis by IBMX augments these effects by elevating the endogenous sperm cAMP concentrations. It is interesting to note that these effects appear most pronounced in the experiments where Ca2+ is depleted (Fig. 4), a condition where Ca2+/calmodulin activated cyclic nucleotide phosphodiesterases might not be expected to be as active. Such Ca2+/calmodulin-stimulated cyclic nucleotide phosphodiesterases have been demonstrated to be present in sperm from a number of different species (Garbers and Kopf, 1980; Tash and Means, 1983; Wasco and Orr, 1984). In addition, the augmentation of protein tyrosine phosphorylation in IBMX-containing medium devoid of added Ca2+ could arise as a consequence of a reduction in the activity of Ca2+-activated phosphoprotein phosphatases, the activity of which is present in sperm (Tash et al., 1988).

Since both Ca2+ and NaHCO3 have been linked to capacitation and the regulation of mammalian sperm cAMP metabolism (Kopf and Gerton, 1991) and this intracellular second messenger has been implicated in both mammalian sperm capacitation and the acrosome reaction, we were also interested in determining whether these membrane permeable cAMP analogues could support capacitation in the absence of these ions. The results shown in Fig. 3 shows this to be the case in the experiments performed in media devoid of NaHCO3. However, in the case of complete Ca2+ depletion (i.e., BSA depletion) experiments (Figs 5 and 7, respectively), the membrane permeable cAMP analogues do not completely restore the ZP-induced acrosome reaction under conditions where protein tyrosine phosphorylation appears to be completely restored (see Figs 4 and 6 respectively). This could be due to the fact that final stages of capacitation, presumably either independent of or downstream of the protein tyrosine phosphorylations, are not being completed, and/or Ca2+ and BSA are important components for the induction of the acrosome reaction (Fraser, 1985; Yanagimachi, 1994). Presently, it is impossible to distinguish experimentally between these two possibilities. In any event these results are consistent with a role for cAMP in the capacitation process, as concluded by other groups (Fraser, 1981; Perreault and Rogers, 1982; Berger and Clegg, 1983; Stein and Fraser, 1984; Monks et al., 1986; Fraser and Monks, 1990). The role of this intracellular messenger in capacitation is further supported by the inhibitory effects of H-89 on capacitation, as assessed by the appearance of the CTC pattern B, the ability of the sperm to undergo a ZP-induced acrosome reaction (Fig. 10), and the ability of the sperm to fertilize ZP-intact eggs (Fig. 11).

As discussed in the accompanying manuscript (Visconti et al., 1995), it is of interest that the sperm appears to intrinsically control events leading to capacitation and that the controlling factor(s) related to this maturational process may lie within the plasma membrane. Destabilization of the plasma membrane by changes in membrane fluidity could ultimately set in motion a series of intrinsic pre-programmed membrane and intracellular events that ultimately regulate those sperm functions that are normally associated with the capacitated state (e.g., changes in sperm motility; ability to undergo a ZP-induced acrosome reaction). Our data would not only support the idea that protein tyrosine phosphorylation might represent a key set of signaling events that are entrained as part of the onset of the capacitated state but that there appears to be a regulatory hierarchy that involves PKA.

Fig. 12 provides a working model for how such changes at the level of the sperm plasma membrane might engage a cAMP-dependent pathway that leads to protein tyrosine phosphorylation and the concomitant endpoints of capacitation. In this model, serum albumin, by virtue of its ability to serve as an extracellular sink for sperm membrane cholesterol efflux (Davis, 1976, 1980; Davis et al., 1979a,b; Go and Wolf, 1985; Langlais and Roberts, 1985), could lead to alterations in membrane fluidity with resultant changes in the permeability of the sperm to Ca2+ (Singh et al., 1978; Rukunudin and Silver, 1990) and/or HCO3− (Okamura et al., 1988). Changes in the permeability of the sperm towards these ions can then regulate intracellular cAMP concentrations through stimulatory effects...
Fig. 12. Diagramme depicting the mechanism by which sperm surface changes that occur under conditions conducive to capacitation give rise to cAMP-dependent regulation of protein tyrosine phosphorylation and the capacitated state. Incubation of uncapacitated sperm under conditions conducive to capacitation gives rise to changes in the permeability of the sperm to Ca²⁺ and HCO₃⁻ via a change in membrane fluidity or membrane destabilization. These changes in membrane properties are thought to occur by the loss of cholesterol from the membrane; this loss may be accelerated by the presence of serum albumins, which can bind cholesterol. As a consequence of the increase in Ca²⁺ and HCO₃⁻ permeability, cAMP metabolism is altered. This could occur by the Ca²⁺ and/or HCO₃⁻-induced activation of adenylyl cyclase (AC), resulting in an increase in intracellular cAMP. Ca²⁺ could also alter the hydrolysis of cAMP by stimulating the activity of a cyclic nucleotide phosphodiesterase(s) (PDE). The increase in cAMP then results in the activation of protein kinase A (PK-A) which leads to the activation of sperm tyrosine kinase(s) (STK) and/or inactivation of phosphoprotein phosphatases, the net result being an increase in protein tyrosine phosphorylation. As a consequence of an increase in protein tyrosine phosphorylation, events leading to capacitation and/or hyperactivation of motility are initiated. In this model capacitation and hyperactivation may or may not be coupled to one another. Arrows with dashed lines indicate hypothetical/uncategorized pathways of regulation. Arrows with solid lines indicate characterized pathways of regulation observed in sperm. +, indicates positive regulation; −, indicates negative regulation.

on adenylyl cyclase. Adenylyl cyclase could be regulated either directly by Ca²⁺ (Hyne and Garbers, 1979) or via calmodulin (Kopf and Vacquier, 1984; Gross et al., 1987). Moreover, sperm cAMP concentrations could be additionally modulated by Ca²⁺ at the level of a Ca²⁺/calmodulin-stimulated cyclic nucleotide phosphodiesterase. Adenylyl cyclase could, likewise, be regulated by HCO₃⁻, as we have demonstrated in Fig. 1 and has been also demonstrated in sperm from other species (Garty and Salomon, 1987; Okamura et al., 1985; Garty and Salomon, 1987; Okamura et al., 1985; Visconti et al., 1990). The resultant changes in cAMP would modulate the activities of PKA, of which there appears to be both Types I and II present in mouse sperm (Visconti and Kopf, unpublished observations), and such changes in enzyme activity would lead ultimately to changes in protein tyrosine phosphorylation.

The endpoints of capacitation that such tyrosine phosphorylations might regulate are also unknown. Changes in sperm motility appear to accompany capacitation process (Neill and Olds Clarke, 1987; Olds Clarke, 1990). Since it is known that cAMP plays an important regulatory role in the initiation of flagellar motility (Tash and Means, 1983) and in alterations of the flagellar curvature (Lindemann and Kannus, 1989; White and Aitken, 1989; Lindemann et al., 1991; Si and Okuno, 1993), it is possible that such cAMP-dependent changes in protein tyrosine phosphorylation might be related to these motility changes. For example, it has been demonstrated that the initiation of flagellar motility in the sperm of the rainbow trout is accompanied by the tyrosine phosphorylation of a 15,000 Mr flagellar protein that occurs in a cAMP-dependent manner (Hayashi et al., 1987). This protein and the tyrosine kinase that regulates its phosphorylation have yet to be identified. It is also possible that changes in tyrosine kinase and/or phosphoprotein phosphatase activities and resultant protein tyrosine phosphorylations are involved in the regulation of ion channels (Siegelbaum, 1994 and references therein). It is interesting to note that the regulation of the voltage-gated cation channel in Aplysia bag neurones by tyrosine phosphorylation appears to be modulated in a cAMP-dependent manner (Wilson and Kazmerek, 1993).

Perhaps the most intriguing observations that have resulted from these studies are that the protein tyrosine phosphorylation state in mouse sperm appears to be regulated by cAMP through the action of PKA. To the best of our knowledge, these observations provide the first example of an up-regulation of protein tyrosine phosphorylation by cAMP/PKA, and suggests that there is cross-talk at some level between PKA and tyrosine kinase/phosphoprotein phosphatase signaling pathways in the sperm. Evidence exists for the down regulation of receptor tyrosine kinase actions by cAMP (Wu et al., 1993; Cook and McCormick, 1993) but up-regulation has thus far not been demonstrated. Protein tyrosine phosphatase activity has been demonstrated to be both inhibited (Begum et al., 1992) and stimulated (Brautigan and Pinnault, 1991) by cAMP, effects of which could ultimately modulate the levels of protein tyrosine phosphorylation. The level at which cAMP/PKA functions to regulate the steady state levels of protein tyrosine phosphorylation in mouse sperm under conditions conducive to capacitation (i.e., tyrosine kinases; phosphoprotein phosphatases) will be the subject of intense scrutiny in our laboratory for the foreseeable future. Subsequent investigations into the mechanism by which cAMP/protein kinase regulates those tyrosine kinases/phosphoprotein phosphatases might yield new information about alternative modes of cross-talk between these two signaling pathways.
