Summary

The inner plexiform layer (IPL) of the vertebrate retina comprises functionally specialized sublaminae, representing connections between bipolar, amacrine and ganglion cells with distinct visual functions. Developmental mechanisms that target neurites to the correct synaptic sublaminae are largely unknown. Using transgenic zebrafish expressing GFP in subsets of amacrine cells, we imaged IPL formation and sublamination in vivo and asked whether the major postsynaptic cells in this circuit, the ganglion cells, organize the presynaptic inputs. We found that in the lak/ath5 mutant retina, where ganglion cells are never born, formation of the IPL is delayed, with initial neurite outgrowth ectopically located and grossly disorganized. Over time, the majority of early neurite projection errors are corrected, and major ON and OFF sublaminae do form. However, focal regions of disarray persist where sublaminae do not form properly. Bipolar axons, which arrive later, are targeted correctly, except at places where amacrine stratification is disrupted. The lak mutant phenotype reveals that ganglion cells have a transient role organizing the earliest amacrine projections to the IPL. However, it also suggests that amacrine cells interact with each other during IPL formation; these interactions alone appear sufficient to form the IPL. Furthermore, our results suggest that amacrines may guide IPL sublamination by providing stratification cues for other cell types.

Introduction

Neural circuits with specific functions are frequently organized into laminae or columns within the vertebrate central nervous system (Sanes and Yamagata, 1999; Wong and Lichtman, 2002). For example, in the visual system, projections from the two eyes are segregated into eye-specific laminae in the dorsal lateral geniculate nucleus and into ocular dominance columns in the visual cortex. A layered arrangement of synaptic connections is also found in the tectum of birds and fish and in the dorsal spinal cord and hippocampus of mammals (Sanes and Yamagata, 1999). The relative importance of neural activity in establishing laminar and columnar patterns of synaptic connectivity during development is still debated (Constantine-Paton et al., 1990; Katz and Shatz, 1996; Katz and Crowley, 2002; Zhang and Poo, 2001). However, pre- and postsynaptic cell-cell interactions before and during synapse formation are widely thought to play an important role in this process (Wong and Lichtman, 2002).

The highly laminated structure of the retina makes it an ideal model system for studying the mechanisms of synaptic layer formation. In the mature inner plexiform layer (IPL; Fig. 1A), connections between retinal ganglion cells (GCs) and their presynaptic partners, the amacrine cells (ACs) and bipolar cells (BCs), are broadly segregated into ON or OFF sublayers, each representing circuits that are either depolarized (ON) or hyperpolarized (OFF) by increased illumination (Famiglietti and Kolb, 1976). The ON and OFF sublayers are further divided into functionally specialized sublaminae (e.g. Roska and Werblin, 2001; Wässle and Boycott, 1991). The IPL and its sublaminae extend continuously across the retina, a feature that is important for lateral processing of visual information. Elucidating the mechanisms underpinning IPL formation and sublamination will provide important insights into how neural circuits become precisely wired during development.

GCs are the earliest cell type to differentiate in the vertebrate retina, followed closely by ACs with whom they form the first synaptic circuits (reviewed by Livesey and Cepko, 2001) [also shown in zebrafish (Hu and Easter, 1999; Schmitt and Dowling, 1999)]. Later, BCs differentiate and synapse onto GCs and ACs, conveying photoreceptor signals to the inner retina. Although it is evident that the developing dendrites of GCs undergo a structural refinement that gradually restricts them to specific IPL sublaminae (Maslim and Stone, 1988; Bodnarenko and Chalupa, 1993; Bodnarenko et al., 1995), it is...
not known whether the neurites of ACs grow directly into a specific IPL layer or whether structural rearrangements are part of the process by which AC arbors find their appropriate laminae. Furthermore, it is unclear whether AC and BC axonal terminals are sculpted on a scaffold initially laid down by GC dendrites or are otherwise dependent on GC-derived cues. Günhan-Agar et al. (Günhan-Agar et al., 2000) and Williams et al. (Williams et al., 2001) showed that, in rats and ferrets, ACs and BCs develop and maintain ON and OFF stratification patterns after experimentally induced degeneration of GCs.

Günhan-Agar et al. (Günhan-Agar et al., 2000) and Williams et al. (Williams et al., 2001) showed that, in rats and ferrets, ACs and BCs develop and maintain ON and OFF stratification patterns after experimentally induced degeneration of GCs. Although elegant in design, these experiments do not unequivocally rule out a role for GCs in IPL organization, because GCs were present and had differentiated prior to ablation. Furthermore, some ACs are already stratified at birth in rodents (Reese et al., 2001; Stacy and Wong, 2003), prior to the manipulations that eliminated GCs.

We thus investigated the role of GCs in organizing lamination of the IPL using a zebrafish mutant in which GCs are never present. The *lakritz* (*lak*) gene encodes Atonal homologue 5 (Ath5), a basic-helix-loop-helix-transcription

**Fig. 1.** Subpopulations of ACs express GFP in Pax6-DF4:mGFP transgenic zebrafish lines. (A) Schematic of inner retinal organization in mature vertebrates. Connections between ganglion cells (GCs), amacrine cells (ACs) and bipolar cells (BCs) are localized to the inner plexiform layer (IPL). The IPL is further organized into ON and OFF sublaminae that occupy approximately the inner and outer halves of the IPL, respectively. (B) The construct used to derive Pax6-DF4:mGFP transgenic lines. Expression of the Gap-43GFP fusion protein was driven by a hexamer of the 58 bp *pax6 DF4* element, located downstream of the SV40 poly-A sequence, and by an upstream EF1α promoter. The sequence of the highly conserved DF4 element is shown. (C) Cross-sectional view of GFP+ ACs and their neurites in the IPL of line 220 7 dpf retina. GFP fluorescence is superimposed on a Nomarski image of a section through the eye. Two bright sublaminae are evident in the IPL (see higher magnification image, inset). (D) Digital rotation of a confocal image stack, providing an orthogonal view of a region of inner retina of a line 220 retinal wholemount at 9 dpf. S1 is an optical slice of this field of view showing sparsely distributed GFP+ neurites close to the AC cell bodies. S2-5 are image planes within the boxed region in S1. The two major GFP+ sublaminae are S2 and S4; note also sparse innervation of sublaminae S1 and S5 by GFP+ neurites. (E) Cross-sectional view of the eye of an 7 dpf line 243 fish. (F) Morphology of individual GFP+ cells in line 243. Maximum projection of a confocal image stack (47 μm total) through the inner retina of a retinal whole mount at 35 dpf. (G) Arbor's of a few isolated ACs (1, 2 in F) at an IPL depth closer to the GCL. (H) Digital rotation of the complete image stack providing orthogonal views of cells 1 and 2. Cell 1 has a diffuse asymmetric arbor spanning the thickness of the IPL. By contrast, cell 2 has a radially symmetric arbor stratifying in the ON sublamina. (I-K) Cross-sections of adult line 220 retina immunolabeled for ChAT. The two bright GFP+ laminae in line 220 coincide with the two major ChAT-immunopositive bands in sublaminae S2 and S4. Some, but not all, GFP+ cells are also immunoreactive for ChAT (arrows). GCL, ganglion cell layer; INL, inner nuclear layer; IPL, inner plexiform layer; NV, optic nerve; dpf, days post-fertilization; L, lens.
factor required specifically for the genesis of GCs (Kay et al., 2001; Brown et al., 2001; Wang et al., 2001). In lak mutants, the first wave of retinal neurogenesis, in which GCs are normally made, fails to occur. As a result, progenitors are prevented from adopting the GC fate (Kay et al., 2001). However, ACs and all other cell types differentiate on time, and an IPL is present (Kay et al., 2001). The specificity of this genetic lesion allowed us to analyze the behavior of ACs in the absence of GCs. For this purpose, we generated transgenic zebrafish in which stable subpopulations of ACs express green fluorescent protein (GFP). GFP expression in these lines marks ACs earlier in their development than most other known markers (Pow et al., 1994), allowing us to visualize the dynamic behavior of GFP-labeled AC neurites in vivo from the earliest stages of neurite outgrowth. Because the zebrafish retina develops rapidly, we were able to continuously monitor IPL development from its formation until segregation into ON and OFF sublaminae, providing the first in vivo view of how functionally distinct synaptic layers arise in a CNS structure during development. Our observations reveal that whereas elimination of GCs causes specific temporal and spatial perturbations in IPL formation, amacrine cells can assume a central role in the formation of synaptic laminae in the retina.

Materials and methods

Generation of Pax6-DF4:mGFP transgenic lines

We used a membrane-targeted version of GFP to generate reporter lines that label subsets of ACs. GFP5 (Siemerling et al., 1996) was fused at its N terminal to the first 20 amino acids of zebrafish Gap43. This sequence is palmitoylated at the cysteines in positions 3 and 4 and targets the protein to the membrane (Skene and Virag, 1989; Zuber et al., 1989). The DF4 sequence is a 58 bp enhancer element, isolated from the pEF enhancer located within the first intron of the pax6 locus (Plaza et al., 1995; Kammandel et al., 1999). We found that quail DF4 (kindly provided by S. Saule), when combined with a truncated EF1α promoter, derived from the pESG vector (kindly provided by C.B. Chien and D. Gilmour) (Johnson and Krieg, 1994), or with the endogenous zebrafish pax6 promoter (P0) (Plaza et al., 1995), drives transgene expression in ACs and, in some lines, weakly in GCs (T.R. and H.B., unpublished). The GFP+ AC subpopulation is stable for more than five generations within one line.

The linearized plasmid (Fig. 1B) was injected into zebrafish embryos at the one-cell stage, following standard procedures (Stuart et al., 1988; Higashijima et al., 1997). The injected embryos were selected for transient GFP expression one day later and raised to adulthood. We recovered nine founders from 70 injected fish (13%), a rate within the range of those previously reported for this technology. Founder fish were crossed to non-transgenic fish, and GFP-expressing progeny were raised to generate a stable line. To visualize IPL formation, the experiments in this study were carried out on three lines: Pax6-DF4:mGFPp220, Pax6-DF4:mGFPp243, and Pax6-DF4:mGFPp244. We will refer to these lines as 220, 243 and 244 throughout this paper. We also generated several lines with a similar construct, which was lacking the membrane-targeting signal, but was otherwise identical to the one shown in Fig. 1B. Six of 26 injected fish (23%) transmitted the transgene to the next generation.

Identification of lak mutants

Homozygous lak mutant embryos (lakh241/h241) (Kelsh et al., 1996) were identified at 2 days post-fertilization (dpf) in live imaging experiments by the abnormal laminar position of GFP+ ACs. This method was validated by RFLP genotyping for the lakh241 allele (Kay et al., 2001). Older larvae were scored as lak mutants based on their visual background adaptation defect, which results in dark pigmentation (Kelsh et al., 1996), or, for some experiments, by immunostaining for GCs (Kay et al., 2001).

Immunocytochemistry

ChAT

Adult 220 transgenic fish were euthanized using Tricaine (0.02% w/v in 0.3×Danieau’s solution). Following decapitation, their eyes were removed and retinas dissected out and fixed in 4% paraformaldehyde (PFA) in 0.1 M phosphate-buffered saline (PBS), pH 7.4, for 2.5 hours. Vibratome sections (50 μm) were cut and incubated in anti-ChAT (AB144P, Chemicon) diluted 1:100 in PBS containing 5% normal donkey serum (NDS) and 0.5% Triton X-100, for 36 hours with gentle agitation. After several rinses in PBS, sections were blocked with 5% NDS in PBS for 1 hour and then incubated in secondary antibody, Alexa 568 donkey anti-goat (Molecular Probes) at 1:1000 in 5% NDS in PBS for 2.5 hours with gentle agitation. After several rinses in PBS, sections were cover-slipped in Gelmount.

PKC

The progeny of a 220/+; lakh241/+ incross were fixed in 4% PFA/PBS at 5 dpf, cryosectioned (12 μm), and immunostained for PKC as described (Kay et al., 2001). Single confocal scans were used to detect PKC immunofluorescence and native GFP fluorescence simultaneously.

GFP

Whole-mount embryos or cryosections were stained as described (Kay et al., 2001) using rabbit anti-GFP (Molecular Probes A-11122; 1:4000 dilution). To permeabilize 3.5 dpf embryos, they were incubated with 0.1% collagenase in PBS for 90 minutes prior to antibody staining.

Live imaging

Embryos/larvae were maintained in embryo medium (0.3×Danieau’s solution with 100 units/ml penicillin and 100 μg/ml streptomycin) at 28.5°C prior to imaging. At 15 hours post-fertilization (hpf), 1-phenyl-2-thiourea (PTU) was added to embryo medium at a final concentration of 0.003% (w/v) in order to block pigmentation in the eye. Prior to imaging, chorions were manually removed and the larvae transferred to a solution of embryo medium containing 0.003% PTU and 0.002% (w/v) Tricaine. Larvae were then embedded in a petri dish (Falcon # 35-3037) in 0.5% low melting point agarose dissolved in embryo medium containing PTU and Tricaine. Dishes were placed in a temperature controlled stage (Cell Microtemp Systems) and recordings were performed at 28-30°C. Typically up to ten fish were aligned in series to enable imaging several fish during each recording session. Images were acquired and presented primarily from the peripheral retina because the lens distorted images of the central-most part of the retina. Confocal image stacks were acquired using either the BioRad 1024M or Olympus FV500. Long working distance water objectives, including 20× Nikon (NA 0.5), 40× (NA 0.8) and 60× (NA 0.9) Olympus objectives, were used. To reconstruct cells and their processes, a series of optical planes were collected in the z dimension (z-stack), and collapsed into a single image (maximum intensity or z-projection) or rendered in three dimensions to provide views of the image stack at different angles. The step size for each z-stack was chosen upon calculation of the theoretical z-resolution of the objective used (typically 0.5-1.0 μm). Time-lapse imaging was carried out by collecting z-stacks encompassing the same cells within a selected region per retina at various intervals (typically once every hour or more, and for total recording periods up to around 40 hours). Image analysis was performed offline, using Metamorph (Universal Imaging) to generate image alignments, orthogonal rotations and movies of the z-stacks.
The Pax6-DF4:mGFP lines permit in vivo imaging of IPL formation and sublamination

Using confocal microscopy, we imaged the eyes of living transgenic zebrafish maintained in a temperature-controlled chamber over several hours to days. In all the transgenic lines, GFP expression is observed in neuroblasts on the first day post-fertilization (dpf), prior to the onset of retinal neurogenesis at 30 hours post-fertilization (hpf; Fig. 2A). As neurogenesis progresses, GFP expression in neuroblasts is diminished and becomes more apparent in ACs. GFP-expressing AC neurites begin to form a plexus parallel to, and approximately two or three cell bodies away from, the internal limiting membrane (ILM) at the beginning of the third dpf (Fig. 2A; 54 hpf). This plexus corresponds to the nascent IPL, as it appears in the expected location and around the time that AC processes first enter the IPL (Schmitt and Dowling, 1999).

Time-lapse imaging revealed that GFP+ AC neurites are progressively added to the forming IPL in a ‘clockface’ progression (Fig. 2B; see Movie 1 at http://dev.biologists.org/supplemental). The nascent IPL recruits neurites from adjacent regions in order to propagate laterally. The progression of IPL innervation trails the anterior-to-posterior wave of AC neurogenesis (Hu and Easter, 1999) by ~10 hours. The GFP+ plexus is initially unstratified; sublamination of GFP-labeled neurites starts in the developmentally more advanced (nasovalental) part of the retina at around 65 hpf and spreads dorsally, again in a clockface progression (Fig. 2C; see Movie 2 at http://dev.biologists.org/supplemental). Sublamination commences at approximately 20 hours after an IPL first becomes visible and is complete throughout the retina by about 90 hpf, an age that roughly coincides with onset of behavioral responses to moving stimuli (Easter and Nicola, 1996).

IPL formation is delayed in lak mutants

We next used lak mutants to ask how the IPL develops in the absence of GCs, the major postsynaptic target of the ACs (Fig. 3; see Movies 3A,B). Our time-lapse recordings revealed that the earliest steps of IPL formation were severely affected in lak mutants. First, we observed a marked delay in the formation of the IPL. As illustrated in Fig. 3, an IPL is present in the wild-type inner retina at 50 hpf but it is not apparent until 55-57 hpf in the lak retinas. Quantitative analysis confirms this observation: Of 45 siblings concurrently imaged from 48 to 85 hpf, an IPL had appeared in 89% of wild-type retinas (32 of 36) at the earliest time point (48-52 hpf). By contrast, only 11% (1/9) of lak mutants in this clutch had developed an IPL by 54 hpf. In a separate experiment, we sorted embryos according to the presence or absence of an IPL at 48-50 hpf. Although 97% of wild-type siblings (33/34) possessed an IPL at this age, only 22% (2/9) of mutants had an IPL, thus supporting our conclusion that IPL appearance is delayed in the absence of GCs. Nevertheless, all lak mutants eventually did develop an IPL, indicating that GCs are not essential for its formation.
forms in lak mutants, its organization is abnormal. GFP+ AC neurites initially elaborate to form an early plexus at, or very close to, the ILM in lak mutants (Fig. 3). This contrasts with the wild-type retina, in which a laterally organized IPL forms several cell bodies away (some 25 μm) from the ILM (Fig. 2A, Fig. 3). The ectopic location and disrupted appearance of the early IPL, more clearly evident at higher magnification (Fig. 4A), was seen in all lak mutants we imaged (n>30 animals). Time-lapse imaging revealed initial AC projection errors in lak mutants to be transient – the nascent IPL translocates outward to assume a more typical position with time (Fig. 4A,B, see Movie 3B at http://dev.biologists.org/supplemental).

As morphogenesis of the IPL continues (between 60-70 hpf), lak mutants begin to show a variable phenotype. Although some stretches of mutant IPL look relatively normal, forming a smooth plexus in the correct orientation parallel to the ILM (Fig. 4E, arrow 1), other patches show several different types of disorganization that are never seen in age-matched wild-type retinas (see Movies 4A-D at http://dev.biologists.org/supplemental). Four main categories of disorganization were seen: (1) gaps in the GFP+ plexus (Fig. 4E, arrow 2); (2) parts of the GFP+ plexus oriented perpendicular or obliquely to the ILM (Fig. 4E, arrow 3); (3) non-laminar agglomerations of GFP+ cell bodies (Fig. 4E, arrow 4) or neurites (Fig. 4C-D,F-G); and (4) AC neurites growing parallel or oblique to the ILM before either joining the IPL (Fig. 4E), or joining with other AC processes outside the IPL (Fig. 4D,F-G). In every mutant retina examined (n>30), the IPL showed all four types of disorganization, although the number of errors, and their degree of severity, was variable. Errors did not seem specific to any one region of the retina. Time-lapse imaging showed that most of these errors were transient: IPL disorganization was most severe at early stages of IPL formation and improved over time (Fig. 3; Fig. 4A,B; see Movie 3B at http://dev.biologists.org/supplemental). Although errors that resemble those of the nascent IPL persist in the mature retina (see below), ACs seem capable of forming a relatively normal IPL without prepattern signals from GCs.

The disorganization of the nascent lak mutant IPL suggests that GCs impart order on AC neurites as they begin to project to the IPL. However, some of the errors we observed in lak mutants appear to result primarily from exuberant growth of ACs towards each other. In particular, the clumping of ACs and their neurites outside the IPL (Fig. 4D-G) suggested that ACs might have a tendency to attract each other. To look more directly for evidence of such cellular behavior, we made time-lapse recordings of line 243 in the lak background. A sample recording shows individual cells that project neurites not towards landmarks such as the ILM or the IPL, but rather towards the neurites of other ACs (see Movie 5 at

---

**Fig. 2.** In vivo visualization of IPL formation and sublamination in Pax6-DF4:mGFP line 220. (A) GFP expression at different stages of development in line 220. At 37 hpf, expression is present in neuroblasts with processes spanning the thickness of the retina. By 54 hpf, GFP expression becomes gradually confined to ACs whose neurites take part in forming a continuous inner plexiform layer (IPL), located approximately four or five cell bodies away from the internal limiting membrane (ILM). GFP expression becomes almost exclusively confined to ACs and their neurites by 71 hpf. Note that anterior retina (left) develops before posterior. L, lens; F, choroid fissure (marks ventral retina). (B) Time-lapse confocal images showing progressive addition of GFP+ ACs over time. Each image is a z-projection of a 19 μm confocal image stack. Arrowheads indicate the same cells in all time frames. Arrow marks the approximate locations of emerging GFP-expression in ACs and neurites that contribute to the forming IPL. (C) Appearance of sublamination in the IPL. Each image is a z-projection of a 3 μm stack of confocal planes. Arrowheads indicate the same region across time points. For (B,C), dorsal retina is towards the right. Time-lapse movies of B and C (Movies 1 and 2) can be found at http://dev.biologists.org/supplemental).
In this movie, neurites from two isolated ACs are seen approaching each other, making putative contact and forming a stable nexus of processes. Notably, each of the cells also appears to make contact with other nearby AC neurites, indicating that agglomeration errors may originate from AC-AC attraction. The lak mutant phenotype, therefore, reveals the existence of both GC-AC interactions and AC-AC interactions during formation of the IPL.

IPL sublamination occurs in the lak mutant, but is locally perturbed

We next turned our attention from IPL formation to sublamination, and asked whether this process is affected by the absence of GCs. We found that sublamination occurs late and is imperfect in lak mutants. By 82 hpf, the GFP plexus of wild-type retina generally shows sublamination, but it rarely does in lak mutants (Fig. 3; also see Fig. S3A,B at http://dev.biologists.org/supplemental). At 4 dpf, however, two distinct sublaminae have formed in mutants, similar to wild type (Fig. 5). With age (7 dpf; Fig. 5), these sublaminae were maintained, and the jagged course of the IPL appears to further straighten. However, unlike wild-type animals where ON and OFF sublaminae are parallel and continuous across the retina, sublamination is locally perturbed in lak mutants. One or both of the sublaminae may be absent (often replaced by a diffuse distribution of GFP+ processes throughout the IPL), or an ectopic sublamina or non-laminar agglomerations may appear locally (Fig. 5). Multiple errors were always seen throughout the retina in every 5-7 dpf mutant eye examined (n=40). Some of these non-laminar clumps resemble structures seen in the nascent IPL of lak mutants (Fig. 4), suggesting that these errors occur early in development and persist to mature stages.

IPL perturbations correlate with projection errors by BCs

BCs are born a few hours later than ACs in the zebrafish retina, and their terminals arrive later in the IPL (Schmitt and Dowling, 1999) (J.N.K. and H.B., unpublished). The local disruptions in AC neuritic organization in lak mutants, therefore, provide an opportunity to determine whether BC axon terminals stratify normally when AC laminae are disrupted. Using an antibody against PKCβ1 (PKC) as a marker for ON BCs (Yazulla and Studholme, 2001; Connaughton, 2001; Kay et al., 2001), we assayed the BC stratification patterns of wild-type and lak mutants in the 220 background. In wild type, PKC-IR terminals are observed in three sublaminae of the ON (proximal) IPL. In lak mutants, the distribution of ON BC terminals is normal in regions where two distinct and orderly GFP+ laminae are present (Fig. 6). However, in regions where the AC projection to the IPL is abnormal, ON BC terminals are either disorganized or, in severely perturbed regions, completely excluded from the ON IPL. BC errors were never observed in regions with normal AC stratification (n=10 lak retinas). These findings suggest that BCs may rely on ACs for stratification cues.

Moreover, the lak BC phenotype suggests that ON BCs may specifically take their cues from ON-projecting ACs. In retinal regions where the IPL perturbations correlate with projection errors by BCs.
ON BCs and ACs showed severe phenotypes, the OFF AC layer was frequently observed to be relatively normal (Fig. 6). In this (Fig. 6) and several other examples, some PKC-IR BC terminals appear coincident with a fainter band of GFP+ neurites ectopically located adjacent to the inner nuclear layer. It could be that the sublaminae are locally inverted here, i.e. these ectopic neurites may arise from ON ACs. If so, this raises the possibility that targeting of the ON BC terminals follows the lamination patterns of ON ACs.

**The effect of the lak mutation on AC sublamination is cell-nonautonomous**

Is the absence of GCs sufficient to explain the lak IPL phenotype? The lak/ath5 gene is transiently expressed in most or all retinal progenitors, including those that generate the ACs (Masai et al., 2000) (J.N.K. and H.B., unpublished). It is therefore important to investigate whether the AC IPL phenotype is really due to absence of GCs, or whether the lak mutation affects ACs directly. To address this issue, we created lak/wild-type chimeras by transplanting small groups of cells from 220 carriers into non-transgenic embryos (Ho and Kane, 1990). We then fixed the chimeras at 4 dpf and inspected their retinas in whole mount for the presence of single GFP+ cells (Fig. 7A-F). We found that all wild-type ACs transplanted into a wild-type retina were monostratified, either in the presumed ON or in the presumed OFF layer (n=28 cells from 12 eyes; Fig. 7A,B,G). When lak ACs were transplanted into wild-type retina, their morphologies were indistinguishable from wild type (n=8 cells from 4 eyes; all monostratified; Fig. 7C).

However, wild-type ACs transplanted into a lak mutant retina occasionally (2/7 cells) had diffuse or bistratified processes. These results suggest that the projection phenotype of an AC is determined not by its own lak genotype, but by that of the surrounding cells.

By sectioning chimeric animals at 7 dpf, we were able to analyze stratification of more donor-derived neurites per eye than was possible in wholemounts (Fig. 7G-J). This approach confirmed our initial findings: When wild-type or lak cells were transplanted into wild-type retina, we always observed GFP+ neurites confined to specific sublayers of the IPL (n=8 eyes for each condition; Fig. 7G,H). However, when wild-type or lak cells were transplanted into lak retina, in every case we observed some GFP+ neurites spreading diffusely throughout the IPL (n=4 eyes for each condition; Fig. 7I,J). This analysis demonstrates that the AC sublamination defects seen in the lak mutant retina are cell-nonautonomous and are in all likelihood caused by the absence of GCs.

**Discussion**

Laminated tissues provide an ideal system for studying how neurites choose specific synaptic targets in the CNS. Here, taking advantage of the optical clarity and rapid development of zebrafish embryos, we have investigated the genesis of synaptic laminae in the retina. To our knowledge, our study is the first to capture the morphogenesis of a layered synaptic structure in vivo.

The zebrafish lak/ath5 mutant provides a unique...
experimental situation in which the major postsynaptic cells of the inner retina, the GCs, are never present. Loss of ath5 function causes a cell-fate switch that blocks GC formation and increases the number of BCs (Kay et al., 2001). However, increased BC density is unlikely to explain the AC phenotypes we report here, because these phenotypes can be observed even before BCs begin innervating the IPL (Schmitt and Dowling, 1999). The number of Pax6-DF4:GFP+ ACs is not increased in lak mutants (Kay et al., 2001). Our cell transplantation experiments further convince us that the lak mutant can be used as a specific tool to study the effects of GC ablation on IPL development.

Time-lapse imaging of GFP-labeled AC neurites revealed the dynamics of IPL formation and ON/OFF sublamination in wild-type and mutant retinas. These studies demonstrate a previously unrecognized role for GCs in positioning and orienting AC neurites during their initial outgrowth towards the IPL. Our studies also highlight, however, the importance of ACs in IPL assembly: ACs can form the IPL on their own, and they appear to provide sublaminar targeting cues to their synaptic partners.

Migration and somal positioning of ACs are influenced by GCs

GCs are well placed to guide the migration of newborn ACs because they are the first cell type to differentiate in the vertebrate retina. In wild type, the early IPL invariably forms at the interface of GCL and the AC layer. In lak mutants, IPL formation begins in an ectopic location, next to the ILM. However, as ACs migrate towards the inner retina and take up

![Image of experimental results](image-url)
IPL formation in the absence of ganglion cells

positions adjacent to the ILM, the IPL is repositioned towards the outer retina (see Fig. 8E,F for a model). These observations raise the possibility that GCs normally restrict the majority of ACs from migrating into the GCL.

AC projections to the IPL are initially guided by cues from GCs

We observed two phenotypes in the lak mutant, suggesting that GCs influence the early outgrowth of AC processes. First, lak mutants show delayed IPL formation. This is not likely to be an effect of the lak mutation on the timing of neurogenesis, because we showed previously that AC differentiation begins on time despite the failure of GC specification (Kay et al., 2001). Rather, this phenotype suggests that GCs may present a signal that promotes neurite outgrowth from ACs. Alternatively, it may be organization of AC neurites into a detectable plexus, not neurite outgrowth, that is delayed in the absence of GCs.

Second, the disorganization of the AC projection in the lak mutant suggests that signals from GCs are important for AC neurite guidance. This phenotype is not caused by the absence of Ath5 in ACs, as shown by our transplantation experiments. One possibility is that the GC-derived signals act at a distance to orient AC growth towards the nascent IPL (Fig. 8D); another possibility is that contact between AC and GC neuritic processes stabilizes appropriately directed neurites while destabilizing misguided ones.

The severe IPL phenotype seen in lak mutants contrasts with the relatively mild effects of GC ablation by optic nerve transection (Günhan-Agar et al., 2000; Williams et al., 2001). In the latter studies, GCs form but are experimentally killed in newborn rats or ferrets. We suggest that the different outcomes of these experiments demonstrate that even transient presence of GCs can pattern the IPL.

ACs can form the IPL alone

GC-derived cues are not the only signals capable of guiding AC neurites, given that many ACs in lak mutants either project normally to the IPL or correct their early errors (Schmitt and Dowling, 1999) (J.N.K., A.M. and H.B., unpublished). Similarly, Müller glia differentiate too late to
possibility, that AC-AC attraction may be sufficient for IPL AC projections. However, our observations suggest another possible that interactions with neuroepithelial cells might guide during development. We found that the nascent IPL is not

orienting early outgrowth, whereas the attractive influence of GCs may be most important for positioning somata and assembly of the wild type IPL (Fig. 8). The interaction with ACs interact with GCs, and with each other, during morphogenesis between 60 and 70 hpf that results in the obviously stratified (Fig. 2C) but over a period of about 10 hours, distinct ON and OFF sublaminae form. Sublamination sweeps across the retina in approximately the same spatiotemporal pattern that characterizes the wave of AC neurogenesis, as has recently been suggested from static images of the chick retina (Drenhaus et al., 2003). This behavior suggests that sublamination may occur at a fixed time after cell specification. Alternatively, there may be a progressive mechanism for sublamination that propagates through the IPL in a wave-like manner. In either case, our recordings have revealed that the IPL undergoes significant morphogenesis between 60 and 70 hpf that results in the formation of distinct sublayers.

We then asked if sublamination involves interactions between ACs and their major postsynaptic target, the GCs. Our results demonstrate that GCs are dispensable for sublamination of AC and BC projections, as previously suggested by experiments in which GCs were removed postnatally in mammals (Günhan-Agar et al., 2000; Williams et al., 2001). Might other retinal cell types provide signals for AC/BC sublaminar targeting? A mouse mutant lacking BCs shows normal AC sublamination (Green et al., 2003); it therefore seems unlikely that ACs receive sublaminar cues from BCs. Müller glia, which first differentiate around 60-70 hpf (Peterson et al., 2001), are another potential source of sublamination cues. Our findings in lak mutants suggest that AC neurites carry at least some targeting cues for their synaptic partners: In areas of the mutant retina where sublaminar information from ACs is degraded or lost, ON BCs fail to target correctly. Recent molecular studies suggest that these AC-derived cues could take the form of homophilic cell adhesion molecules, such as Ig-superfamily molecules or cadherins (Yamagata et al., 2002; Masai et al., 2003).

**ACs may drive IPL sublamination**

We used line 220 to investigate how sublamination arises during development. We found that the nascent IPL is not...
Despite the fact that GCs are not essential for sublamination, the IPL is not completely normal in lak mutants – we found that sublamination is globally delayed, and that it fails altogether in local retinal patches. Such findings are consistent with the possibility that GCs provide one of several signals that influence sublamination. However, we think it is more likely that the presence of GCs is permissive: GCs may provide a scaffold that organizes the early IPL, setting the stage for a GC-independent sublamination process. According to this model, the initially-disorganized IPL that forms in the absence of GCs needs time to ‘recover’ (self-correct by AC-AC interactions) before sublamination can start. That recovery does occur is shown by our time-lapse images – the unevenness and disorganization of the lak mutant IPL clearly improves with time. The retinal patches where sublamination fails may correspond to places where the early disorganization does not recover sufficiently to allow sublamination – for example, in places where an ectopic aggregate of AC processes has formed (see model in Fig. 8).

**Targeting without a major target**

Our finding that the presence of a major class of postsynaptic neurons is dispensable for the proper arrangement of presynaptic terminals is not without precedent. In the *Drosophila* optic lobe and the mouse entorhinal–hippocampal projection, afferents depend on a transient intermediate target rather than the eventual postsynaptic neuron for correct projection, afferents depend on a transient intermediate target. The retinal patches where sublamination fails may correspond to places where the early disorganization does not recover sufficiently to allow sublamination – for example, in places where an ectopic aggregate of AC processes has formed.
