Summary
During gastrulation, optimal adhesion and receptivity to signalling cues are essential for cells to acquire new positions and identities via coordinated cell movements. T-box transcription factors and the Wnt signalling pathways are known to play important roles in these processes. Zebrafish tbx2b, a member of the TBX2 family, has previously been shown to be required for the specification of midline mesoderm. We show here that tbx2b transcripts are present during mid-gastrula before its expression is detected by whole-mount in situ hybridization. Isolated ectodermal cells deficient in Tbx2b have altered cell surface properties and the level of cadherins in these cells is lower. In chimaeric embryos generated by cell transplantation and single blastomere injections, Tbx2b-deficient cells are defective in cell movement in a cell-autonomous manner, resulting in their exclusion from the developing neural plate. Using this ‘exclusion’ phenotype as a screen, we show that Tbx2b acts within the context of Fz7 signalling. The exclusion of cells lacking T-box proteins in chimeras during development was demonstrated with other T-box genes and may indicate a general functional mechanism for T-box proteins.

Key words: T-box, Cell adhesion, Zebrafish, Frizzled 7, Dishevelled, DIX domain, β-catenin

Introduction
During gastrulation, concurrent cell movement and cell fate specification eventually lead to the formation of germ layers and axes in the embryo. Because zebrafish embryonic cells are pluripotent up to the early gastrula stages (Ho and Kimmel, 1993), alteration of cell movement can cause changes in fate specification by virtue of exposure to local signalling cues prevalent in the ‘adopted’ position. Conversely, a failure in fate specification can lead to changes in cell movement behaviour.

In the zebrafish ectoderm, individual cells lose their independence and integrate their behaviour to achieve a coherent movement over the yolk as a sheet (Concha and Adams, 1998), while the underlying mesodermal cells migrate as individuals or groups of cells. This is in contrast to Xenopus, where the ectoderm is tightly coupled to the mesoderm (Shih and Keller, 1994). Optimal cell adhesion is essential for proper cell movement (Nelson and Nusse, 2004). Cell-surface adhesion molecules such as cadherins control cell-cell adhesion and influence cell migration. Disparity in cell adhesion properties among neighbouring cells is known to lead to loss of integrity and cell sorting within the ectodermal sheet (Concha and Adams, 1998).

The embryonic ectoderm has the potential to acquire either epidermal or neural fates. According to the default model, neural induction depends on the suppression of bone morphogenetic protein (Bmp, vertebrate homologue of Dpp) signalling by organizer-derived inhibitors (Munoz-Sanjuan and Brivanlou, 2002). Mass cell movements during gastrulation, especially that of convergent extension (CE), eventually establish the neural plate, which can be differentiated from the remaining epidermal ectoderm by early neural markers such as sox19 (Vriz and Lovell-Badge, 1995). CE movement is most extensively investigated at the molecular level within the context of mesoderm formation (Myers et al., 2002). As such, the molecular mechanism governing dorsal movement of the overlying ectoderm leading to the formation of the neural plate is not well understood.

In Xenopus, Wnt/β-catenin has been demonstrated to inhibit Bmp (Baker et al., 1999) and is required for the expression of secreted Bmp antagonists (Wessely et al., 2001). In the zebrafish, Wnt/β-catenin-dependent bozozok (boz) is sufficient to suppress expression of bmp (Fekany-Lee et al., 2000). This is consistent with the role of β-catenin-dependent Wnt signalling, or canonical Wnt signalling, in fate determination (Moon et al., 2002). β-Catenin-independent Wnt signalling, or non-canonical Wnt signalling, has been demonstrated to influence morphogenetic cell movement (Tada et al., 2000; Heisenberg et al., 2000) by controlling Dishevelled (Ds)-mediated polarity in a manner reminiscent of the Drosophila planar-cell-polarity (PCP) pathway. However, in addition to its function in the Wnt signalling pathway, β-catenin also binds to the cytoplasmic domain of type 1 cadherins and plays an essential role in the structural organization and function of cadherins in the actin cytoskeleton (Jamora et al., 2003). Different cadherins have been shown to stimulate directly the
differentiation of stem cells into specific tissues (Larue et al., 1996). As such, there is a possible convergence of Wnt, β-catenin and cadherin signalling in adhesion, morphogenetic movement and differentiation.

Transcription factors of the T-box family (Tbx) play important roles in vertebrate development (Smith, 1999; Wilson and Conlon, 2002). Brachyury (T) and the zebrafish orthologue no tail (ntl) are known to be essential for the specification of axial mesoderm (Smith, 1999). In addition, T, Tbx16/spadetail (spt) and Xbra have been shown to be required for mesodermal cell movement (Wilson and Beddington, 1997; Ho and Kane, 1990; Kwan and Kirschner, 2003). A number of human disorders have been linked to mutations in T-box genes, confirming their medical importance (Packham and Brook, 2003). Recently, a knockout of TBX2 in mice resulted in abnormal development of the heart (Harrelson et al., 2004).

Ntl is shown to function in parallel to Wnt5 signalling in the morphogenesis of the posterior body (Marlow et al., 2004) and Xbra is shown to regulate Wnt11 expression during gastrulation (Tada and Smith, 2000). The Drosophila Tbx2-related opto-motor blind (omb) is regulated by the Wingless (Wg), Decapentaplegic (Dpp) (Grimm and Pfugfelder, 1996) and Hedgehog (Hh) (Kopp and Duncan, 1997) signalling pathways; Xenopus Tbx2 is known to function within the Sonic hedgehog (Shh) pathway (Takabatake et al., 2002); in chick, Tbx2 is known to function through both Shh and Bmp signalling (Suzuki et al., 2004).

Zebrafish tbx2b was previously named tbx-c. Using a dominant-negative (dn) approach, it was shown to function downstream of Tgfβ signalling, of ntl and of floating head (fhb) in the late-phase specification of the notochord and development of motoneurons (Dheen et al., 1999). In this report, we show that neural development is dependent on early Tbx2b activity during gastrulation. Using a combination of antisense morpholino oligonucleotide (MO) gene ‘knockdown’ (Nasevicius and Ekker, 2000) and in vivo analysis of chimerae embryos generated by cell transplantation or single blastomere injection, we demonstrate that, during neural plate formation and neuronal specification, Tbx2b functions within the context of Wnt signalling to mediate cell migration.

Materials and methods

Reagents

MOs were obtained from Gene Tools (USA). Sequences were as follows (sequence complementary to predicted start codon is underlined): tbx2b MO, 5'-AGG AAG ATG GTG AAG CCA TCA CAG T-3'; ttxb2 MOv2, used for all data generated in this study, 5'-GTT AAG ACG TCA CAG TCT CGT TAA A-3'; f7 MO, 5'-ATA AAC CAA AAA AAA CCT CGT C-3'; f7a MO, 5'-CCA ATC TGG AGC TCC AGA GGC C-3'; f2 MO, 5'-ACA AAA TGA GTC CGG CAA ACT ATG C-3'; axin1 MO, 5'-CAT AGT GTC CCT GCA CTC TGT CCC A-3' phenocopies the mutant masterblind; stbm MO is as described (Park and Moon, 2002); ntl MO is as described (Nasevicius and Ekker, 2000); b-jun MO, 5'-ACT CAT AGA GTT GGA AAA CCG GTG G-3' c-jun MO, 5'-TTT AGG CCG TGT TAA GCA CTC TCC G-3'. Stocks (1 mM) were made in Danieau’s solution. Pertussis toxin was obtained from Sigma (P2980, 200 mg/ml).

Whole-mount in situ hybridization, immunohistochemistry, western blot and TOP-Flash assay

Whole-mount in situ hybridization and whole-mount immunohistochemistry with anti-fluorescein-POD were performed according to established techniques. Proteins were extracted from 20 embryos/lane for western blot, and detected with chemiluminescent detection kit (Cell Signalling Technology, USA). TOP-flash assay was performed as described (Korinek et al., 1997).

Dominant negative Fz7-EGFP/BAC construct

Dn-f7 targeting construct was generated from f7 cDNA by replacing the stop codon with an EGFP-kanamycin cassette using overlapping amplimers and primer extension. Primer sequences were as follows: 5’UTRF, 5’-AGG AAA CCG CAC TCT TGT CA-3’; f7R, 5’-TAC CGT CGT CTC GCC CTG GTT-3’; f7EGFP, 5’-CGG AGC AGG AGC GTA ATG GTG AGC AAG GGC-3’; kanR, 5’-TCA GAA GGA CTC GTC AAG AAG GCG ATA GAA-3’; kan3’UTRF, 5’-CTT CTT GAC GAG TTC TTC TGA AAA AAA GAG GAG CTC TTT TCG-3’; and 3’UTR, 5’-ACA ATG CCC CCG TTA AAA CAA GTG TTG G-3’. The resultant dnf7-EGFP construct was co-transformed with pGTErec into E. coli DH10B carrying a BAC of the intronless f7 gene. Homologous recombination was then induced (Narayan et al., 1999).

Transplantation

Donor embryos were injected at the one-cell stage with fluorescein dextran pre-mixed with MO or Danieau’s solution. About 20 cells from each donor were transplanted into wild-type host embryo of the same stage. Chimaeric embryos were grown to 10 and 24 hpf. Location of transplanted cells at 10 hpf was visualized by a combination of immunohistochemistry with anti-fluorescein-POD and sox19 whole-mount in situ hybridization. Images were taken using the Olympus AX70 (Olympus, Japan) microscope fitted with CCD camera. Fluorescent and bright-field images were superimposed with Photoshop 5.5 (Adobe) software.

Injections at 16 cell stage

Dechorionated 16-cell stage embryos were transferred to a Petri dish with moulded agar (1.5% agarose in egg water) injection wells and one central blastomere was injected with not more than 200 pl of reagents. Injected embryos were allowed to develop to 4 hpf, and then were inspected under a UV dissecting microscope. Embryos with labelled clones in the centre of the blastoderm, when viewed from the animal pole, that represented a perfect cone when viewed from the side, were allowed to develop further. In this way only ectodermal derivatives were labelled.

Real time RT-PCR

Total DNA-free RNA (1 mg) was subjected to oligo(dT)15 primed RT with PowerScript Reverse Transcriptase (Clontech) according to the manufacturer’s recommendations, and 1/20 of the reaction mix was used for PCR. Real-time semi-quantitative PCR assay was carried out using gene-specific primers for ttxb2b (forward, 5’-AGG AAC CCG TTC TTG AGC AGC-3’; reverse, 5’-AGG CGT GCC GTT GAC AAT CCG GTG-3’), EF1α (forward, 5’-AGA CTG GTG TTC TCA AGG CTC-3’; reverse, 5’-TCA AGT TGG CAG CCT CCA TGG-3’) and f7 (forward, 5’-TCA CTG TGG TCT TAC AAA CGA CGC-3’; reverse, 5’-TGC ACT TCG AGA CCG GCG TTC-3’) in a DNA Engine Opticon System (MJ Research, USA). SYBR Green was used as the reporter for real-time PCR. Briefly, HotStart Taq (Qiagen) activation for 15 minutes, four segment amplification and quantification program repeated 35 times [95°C for 30 seconds; 62°C for 10 seconds with a single fluorescence measurement; 72°C for 30 seconds, melting curve program (78°C to 95°C)]. Serial dilutions of cDNA were used as standards for semi-quantitation. Correction for inefficiencies in RNA input or reverse transcriptase was performed by normalizing to EF1α.
amplification. The comparative C(T) method, calculating relative expression levels compared to control, was used for quantification.

**Hanging-drop culture**

Hanging-drop cultures were carried out with animal caps from embryos at 50% epiboly as previously described (Steinberg and Takeichi, 1994). Fluorescent images were obtained with a Zeiss Axioplan2 equipped with Zeiss AxioCam HRc CCD camera (Zeiss, Germany).

**Results**

RT-PCR showed that *tbx2b* transcripts are not maternally supplied and appear only at 50% epiboly (5.5 hpf, Fig. 1A and data not shown). Real-time PCR measurements of the level of transcripts in the dorsal and ventral half of 5.5 hpf embryos (when the shield could be seen with confidence) indicated that *tbx2b* is present at a higher level in the ventral blastoderm than the dorsal blastoderm (Fig. 1E). By 8 hpf and later, the transcripts accumulate in the dorsal blastoderm and dorsal structures – the notochord and neural derivatives (Dheen et al., 1999). This shift in the distribution of *tbx2b* from ventral to dorsal coincides with the dorsal CE movement of cells during gastrulation.

The initial functional analysis on the role of *tbx2b* in development was performed with a dn-Tbx2b lacking the C-terminal transactivation domain (Dheen et al., 1999). For this study, a MO-mediated loss-of-function approach (targeted gene ‘knockdown’) was adopted. Two anti- *tbx2b* MOs were designed (see Materials and methods). Both straddle the start codon of *tbx2b*, but offset by 10 bases along the 5′-UTR. To establish their efficacy, the two MOs were injected into one-cell stage embryos (pan-embryonic injection). At the same concentration, *tbx2b* MOv2 was more effective in producing a phenotype than *tbx2b* MOv1 and was used for all experiments in this study (henceforth referred to as *tbx2b* MO).

When co-injected with *tbx2b* MO pan-embryonically, translation of a myc-tagged *tbx2b* containing the target site for *tbx2b* MO was blocked in a dose-dependent manner (Fig. 1B). The midline axial mesoderm of the morphants, as analyzed and compared with embryos obtained from overexpression of dn-Tbx2b with the marker *sonic hedgehog* (*shh*), had malformed notochord and lacked the floor plate (Fig. 1C). In the most severely affected morphants, only remnants of the notochord were present (Fig. 1D). This is reminiscent of the mutant *flh*, and is in agreement with our previous study (Dheen et al., 1999). These results suggest that the phenotype observed with *tbx2b* MO was indeed specific to the ‘knockdown’ of *tbx2b*.

Pan-embryonic ‘knockdown’ of *tbx2b* with *tbx2b* MO delayed the onset and progression of gastrulation by up to 2 hours and produced phenotypes at 24 hpf in a dose-dependent manner. In its most severe form (at 1 pmol/embryo), *tbx2b* morphants display phenotypes similar to *boz*/− embryos (Fekany-Lee et al., 2000) – short AP axis, absent or malformed notochord, fused somites, small and/or cyclopic eyes, and small brain (Fig. 1F-G). Cross-sections of the morphants at the level of the eyes showed that the neural tube was severely malformed; the ventricle was absent and the eyes were underdeveloped (Fig. 1H-I). Injections of a sense MO up to 10 pmol showed no phenotype.

The disorganized forebrain of the *tbx2b* morphant supported a role for Tbx2b in neural development. However, the severity of the malformation rendered analyses of pan-embryonic morphants ambiguous. To circumvent this, we analyzed the behaviour of Tbx2b-deficient cells in chimaeric embryos. The chimaeras were generated by two complementary approaches aiming to target ectodermal derivatives – cell transplantation and single-blastomere injection.
Fig. 2. Tbx2b is required for cells to adopt a neural fate. Deep cells from embryos co-injected with fluorescein-dextran (70 kDa) and t bx2b MO at 30% epiboly were transplanted into homochronic wild-type hosts. (A) Cross-section through the neuroretina and brain shows transplanted control labelled cells in the CNS. By contrast (B) transplanted Tbx2b-deficient cells were present only in the epidermis (arrowheads). (C) One central blastomere of 16-cell stage embryos was injected with fluorescein either with or without t bx2b MO, and embryos were allowed to develop to 24 hpf. Both control and t bx2b morphants developed normally and showed a similar distribution of labelled clones in vivo at 3.25 hours. (D) Dorsal view of 24 hpf control embryo shows labelled cells in neural plate and epidermis. (E) t bx2b morphant labelled cells were present only in epidermis. (F,G) Whole-mount in situ hybridization with the pan-neural marker sox19 shows a delay in convergence of the neural plate in t bx2b morphant (arrow in G) compared with control (F). (H-K) Whole-mount in situ hybridization with bmp2 (H,L) and fz7 (J,K) show similar expression patterns in control and Tbx2b morphant at 5 hpf. (L-N) Transplanted fluorescein labelled Tbx2b-deficient cells continue to express sox19 in 5 hpf wild-type host. (N) The merged photographs were enhanced in Adobe Photoshop such that only the simultaneous presence of blue (whole-mount in situ hybridization signal) and green (fluorescence) produced a purple signature. Otherwise, cells remain grey.

Fluorescein-dextran-labelled cells of the animal blastoderm were transplanted from 4 hpf wild-type donor embryos into the same location in homosynchronous wild-type hosts. By 24 hpf, labelled cells were found in the brain, eyes and epidermis (Fig. 2A). In similar transplants, when t bx2b morphant cells were placed in wild-type hosts, the labelled cells appeared only in the epidermis (Fig. 2B), supporting the suggestion that Tbx2b may be required during the formation of the neural plate. To confirm this, a single central blastomere of 16-cell stage embryos was injected (referred to as a 1/16 injection, Fig. 2C) with fluorescein, either with or without t bx2b MO, and the position of the labelled cells determined later. At 3.25 hpf, both control and t bx2b MO-injected embryos showed labelled clones in the ectoderm (Fig. 2C), suggesting that right up to this stage there were no discernible behavioural differences between control and t bx2b morphant cells. However, at 24 hpf, control embryos had labelled cells in the eyes, epidermis and CNS (Fig. 2D), while t bx2b MO injected embryos displayed labelled cells only in the epidermis (Fig. 2E), thus supporting the observations from transplantation experiments.

In both transplantation and single-blastomere injection experiments, there were reduced numbers of Tbx2b morphant cells compared with control. This could arise from an increase in cell death, from a decrease in cell proliferation or from cell loss. Staining of t bx2b morphants with Acridine Orange and TUNEL assay showed no significant increase in apoptosis (not shown). We also failed to observe cell loss because of sloughing during gastrulation, although we could not rule out this possibility later in development. Therefore the reduction in cell count was probably the result of impairment in cell proliferation. This is consistent with reports implicating human TBX2 in cell cycle control and oncogenesis (Jacobs et al., 2000; Prince et al., 2004).

sox19 encodes the early pan-neural transcription factor (Vriz and Lovell-Badge, 1995). It is expressed in the neural plate at 10 hpf (Fig. 2F). In t bx2b morphants the neural plate was broader, with a pronounced gap in expression around the midline (Fig. 2G, arrow). We asked if this was likely to be due to an early defect in specification, and thus focused on at early patterning. The expression patterns of bmp2 and fz7 in control and morphant 5 hpf embryos were similar (Fig. 2H-K), although expression in the morphants appeared to be more punctate than in control embryos. This could be the result of the delayed epiboly in t bx2b morphants. In addition, during gastrulation, transplanted donor cells from t bx2b morphants continue to express sox19 in wild-type hosts at 5 hpf (Fig. 2L-N). These results suggest that early fate specification is not affected by the loss of Tbx2b function; instead, dorsal convergence cell movement was delayed in the morphants.

When 1/16 injected embryos were stained for both fluorescein and sox19 at 10 hpf, control labelled cells were found in the neural plate and epidermis (Fig. 3A). By contrast, Tbx2b morphant cells were excluded from the neural plate (Fig. 3B). This suggested that the lack of labelled cells in the 24 hpf morphants observed in previous experiments was due to the absence of labelled cells in the neural plate at 10 hpf. 1/16 injection of t bx2b mRNA led to the appearance of labelled cells with normal morphology at the midline at 10 hpf, and in the notochord at 24 hpf, in about 10% of the injected embryos (n=30, Fig. 3C,D). Although this result is consistent with the role of Tbx2b in the formation of axial mesodermal structures.
The ‘exclusion’ phenotype points to aberrant cell migration within the embryonic ectoderm, suggesting that cell adhesion could be compromised. The surface of embryos undergoing gastrulation is smooth (Fig. 4A). By contrast, pan-embryonic injections of tbx2b MO (Fig. 4B) caused rounding of cells on the surface of morphants. As a result, the morphants acquired a ‘rough’ phenotype, suggesting that cell adhesion in vivo was affected. Currently, we do not know if there were other cell polarity defects associated with this ‘rough’ phenotype.

To test whether Tbx2b-depleted cells exhibited altered cell adhesion properties, cell re-association experiments were performed. Texas Red-labelled animal caps of 5 hpf embryos from wild-type or MO-depleted embryos were dissociated and mixed with fluorescein-labelled wild-type cells and cultured as hanging-drop. After 24 hours, the two control-derived populations formed a single aggregate (Fig. 4D), suggesting similar surface adhesion properties. By contrast, cells that were co-injected with fluorescein and tbx2b MO (Fig. 4E) formed shells around small aggregates of control cells. This is consistent with the idea that aggregated control cells have higher level of the same cadherin than do morphant cells in the outer shells (Steinberg and Takeichi, 1994).

Cadherins are essential for cell adhesion. Indeed, supporting the observation from hanging-drop culture, the level of cadherin failed to increase during gastrulation in tbx2b morphants (Fig. 4G). This suggests that the deficiency in cadherins could be the proximal cause of the defects in cell adhesion and migration observed in vivo. It is known that during epiboly, cell-cell adhesion plays a crucial role in maintaining the integrity of the ectodermal sheet (Concha and Adams, 1998). Although Xbra is known to inhibit cell migration, it was shown to do so by inhibiting adhesion to fibronectin instead of affecting the level of cadherin directly (Kwan and Kirschner, 2003). The mutation in parachute (pac) eliminates N-cadherin. Similar to tbx2b morphants, this mutant is characterized by abnormal anterior neural tube (Lele et al., 2002). Indeed, cells transplanted from pac into wild-type hosts failed to populate the anterior CNS by 24 hpf (9/9). By contrast, cells from heterozygous siblings were found in the CNS of hosts (10/10).

To demonstrate that migration of cells deficient in Tbx2 is also affected, morphant cells were co-transplanted with control cells into the ectoderm of wild-type embryos and observed in vivo (Fig. 4H-I). The morphant cells lagged behind control cells when migrating to the dorsal side of the embryo at 50% (Fig. 4J) and 80% epiboly (not shown). In addition, by the end of gastrulation, these cells did not express sox19 and remained outside the neural plate at 10 hpf (Fig. 4L). Thus, an essential aspect of neural plate formation is the requirement of Tbx2b for optimal cell adhesion and consequent cell movement into the dorsal ectoderm destined to develop as the neural plate.

The percentage of embryos with an ‘exclusion’ phenotype, where labelled cells arising from 1/16 injection of tbx2b MO were excluded from the neural plate (as defined by sox19 expression) at 10 hpf, was significantly reduced in a dose-dependent manner by co-injection of a tbx2b mRNA lacking the target site for tbx2b MO. This phenomenon was accompanied by the appearance of labelled cells in the midline and the notochord at 10 and 24 hpf, respectively, in about 10% of experimental embryos (Fig. 3E). In all, the results support the specificity of tbx2b MO and demonstrate the early requirement of Tbx2b in the formation of the neural plate.
for efficacy and viability (data not shown). Where available, MOs were tested to phenocopy the respective mutants (see Materials and methods). The assay allowed us to narrow down quickly on a potential pathway.

Consistent with the role of Bmp suppression in neural induction, 1/16 injection of bmp2 mRNA led to ‘exclusion’ phenotype in all experimental embryos. This is in contrast to injection of dn-BmpR, which blocked Bmp signalling (Neave et al., 1997). A 1/16 injection of b-jun and c-jun, known to be involved in CE movement through non-canonical Wnt signalling (Myers et al., 2002), led to complete exclusion, supporting the notion that the ‘exclusion’ phenotype arises from a cell movement defect. A 1/16 injection of PKA (Fig. 4N, a negative regulator of the Hh pathway) (Hammerschmidt et al., 1997) and XFD (Fig. 4O, which blocked FGF signalling) (Schulte-Merker et al., 1995) failed to recapitulate the exclusion phenotype and thus ruled out the involvement of the Hedgehog and FGF pathways upstream of Tbx2b. By contrast, interference of Wnt signalling by overexpression of a dn-Fz7 that lacked the C-terminal intracellular PDZ-binding domain led to the ‘exclusion’ phenotype (Fig. 4P). Detailed analyses showed that a similar effect could be obtained with anti-fz7 MO (fz7 MO, Fig. 4Q), but not with MOs against the closely related fz7a and the more distantly related fz2 (Table 1).

Next, intracellular components downstream of Fz7 were analyzed (Table 1). Dishevelled (Ds) consists of three functional domains: the DIX domain is essential for β-catenin activity, whereas the PDZ and DEP domains are involved in non-canonical signalling (Topczewski et al., 2001). Constructs of Xenopus Ds (Xds) with domain deletions were injected in the 1/16 manner. Of these three constructs, only XdsΔDIX, which lacks DIX domain, phenocopied the exclusion phenotype, suggesting that a disruption of β-catenin signalling could contribute into the ‘exclusion’ phenotype. Indeed, TOP-flash assay of Fz7 morphant embryos indicated a marked decrease in the level of β-catenin-dependent Tcf activity (Fig. 5A). Although MOs against b-jun and c-jun led to exclusion, the inability of the XdsΔDEP (without DEP domain) and XdsΔPDZ (without PDZ domain) to induce exclusion is particularly interesting as the non-canonical pathway is known to function via corresponding domains to activate the JNK/SAPK cascade (Korinek et al., 1997). Owing to the pleiotropic nature of β-catenin and Jun, rescue experiments with tbx2b remain complicated. In summary, the screen showed that interfering with Wnt signalling consistently produced the same effect as depletion of Tbx2. These results led us to focus our analysis on fz7.

fz7 is expressed in the ectoderm during gastrulation (Fig. 5B); thus, it is present in the ectodermal cells at the time when they acquire neural fates. Ectopic overexpression (by intracellular injection of DNA construct into one-cell stage embryos) of a dn-Fz7-EGFP/BAC (with the EGFP inserted into the C terminus to replace the stop codon) caused the loss of tbx2b expression (Fig. 5C). Real-time PCR analysis of tbx2b- and fz7-morphants (MOs injected at 0.5 pmol and 0.2 pmol) failed to recapitulate the exclusion phenotype and thus ruled out the involvement of the...
showed that whereas fz7 MO downregulates fz7 and tbx2b transcription at 5 hpf, tbx2b MO has no effect on the transcription of fz7 and its target mRNA (Fig. 5E).

Further analysis showed that fz7 morphants displayed ‘rough’ phenotype during gastrulation (Fig. 4C), fz7-deficient cells failed to aggregate with control cells in hanging-drop cultures (Fig. 4F), fz7 morphants failed to upregulate cadherins (Fig. 4G), and transplanted fz7-deficient cells did not co-migrate with control cells (Fig. 4K,M). A 1/16 co-injection of tbx2b mRNA with fz7 MO led to the appearance of morphologically undifferentiated labelled cells in the eyes and forebrain at 24 hpf (Fig. 5D), suggesting that Tbx2b is able to rescue the cell movement, but not the fate specification function of Fz7. Owing to the pleiotropic nature of Fz7 function, attempts to rescue the ‘exclusion’ phenotype of fz7 MO by co-injection of a fz7 mRNA without the MO target site were unsuccessful. Together, these results suggest that Tbx2b may function as a downstream effector of Fz7-mediated cell movement during neural plate formation (Djiane et al., 2000).

Is the cell movement defect arising from Tbx2b ‘knockdown’ the direct cause of neuronal specification failure in these cells later in development? To answer this, cells from shield stage (6 hpf) of Tbx2b morphant donors were transplanted directly into the dorsal side of homochronic wild-type hosts at two locations: one that gives rise to the eyes and the other to the hindbrain by 24 hpf (Fig. 5F-G), suggesting that Tbx2b is able to rescue the cell movement, but not the fate specification function of Fz7. Owing to the pleiotropic nature of Fz7 function, attempts to rescue the ‘exclusion’ phenotype of fz7 MO by co-injection of a fz7 mRNA without the MO target site were unsuccessful. Together, these results suggest that Tbx2b may function as a downstream effector of Fz7-mediated cell movement during neural plate formation (Djiane et al., 2000).

However, owing to the delay in the onset and progression of gastrulation in morphants, the donors were not morphologically equivalent to wild-type shield stage embryos (they resembled 4 hpf embryos). To confirm that the failure in specification was not due to the delay in development, transplantation was repeated with cells from morphant donors at shield stage irrespective of the actual age (~8 hpf). Although a few transplanted cells managed to regain the typical morphology of cells in these tissues (arrowheads, Fig. 5H,I), the majority did not. This result suggests that Tbx2b may have a later role in neuronal differentiation. Similarly, we demonstrated that in the absence of Fz7, overexpression of tbx2b could only rescue the cell movement defect but not the
subsequent differentiation of transplanted cells (Fig. 5D). Altogether, these results suggest that, independent of its requirement in cell adhesion and cell movement, Tbx2b is necessary, but insufficient, for neuronal differentiation in the late neuroectoderm. tbx2b is expressed at high levels in sensory cells and other neuronal lineages later in development, and is therefore likely to play a role in their differentiation (Dheen et al., 1999).

Discussion

The previous loss-of-function study using dn-Tbx2b has shown a role for Tbx2b in the notochord (Dheen et al., 1999). In this study, we used morpholino antisense oligos (MO) to effect a ‘knockdown’ of Tbx2b to address its early function in development suggested by the presence of its transcripts as early as 50% epiboly, before they were detected by whole-mount in situ hybridization. The specificity of the MO used was established by its ability to block translation of myc-tagged Tbx2b and produce comparable phenotypes in the notochord demonstrated with dn-Tbx2b.

Pan-embryonic injection of tbx2b MO led to a delay in epiboly and malformed anterior forebrain at 24 hpf. In order to separate analyses in ectoderm from mesoderm, we focused on the behaviour of Tbx2b-depleted ectodermal cells in an otherwise normal wild-type embryo. We demonstrated that cells deficient in Tbx2b were consistently excluded from the neural plate at 10 hpf, and did not develop as neural cells by 24 hpf. Embryonic cells are pluripotent up to the early gastrula stages (Ho and Kimmel, 1993). Therefore, alteration of cell movement can cause changes in fate specification by virtue of exposure to local signalling cues prevalent in the ‘adopted’ position. Conversely, a failure in fate specification can cause a change in cell movement behaviour. Either mechanism could lead to exclusion of cells from the neural plate. However, analysis of expression of bmp2, fz7 and sox19 suggest that early fate specification is not affected by ‘knockdown’ of Tbx2b. Indeed, the neural plate is induced in the Tbx2b morphant. Our results thus indicate that Tbx2b functions in cell migration in the ectoderm during the formation of the neural plate.

It has been shown that strong intercellular adhesion plays a crucial role in maintaining the integrity of the gastrulating ectodermal sheet (Concha and Adams, 1998). In zebrafish null mutant for N-cadherin (pac), neuroectodermal cell adhesion is altered, leading to compromised convergent cell movements during neurulation (Lele et al., 2002). We show that cells depleted of Tbx2b have reduced cadherins, and this altered cell adhesion is likely to be the cause of migration defects leading to their exclusion from the neural plate in chimeras. As β-catenin binds tightly to the cytoplasmic domain of type 1 cadherins (Jamora et al., 2003), loss of cadherins in Tbx2b-depleted cells may lead to defects in β-catenin stabilization and localization, with subsequent consequences in differentiation. As such, there is a possible convergence of Tbx2b, Wnt, β-catenin and cadherin signalling in adhesion, morphogenetic movement and differentiation.

Although spt (Ho and Kane, 1990), T (Wilson and Beddington, 1997),ntl (Conlon and Smith, 1999) and Tbx5 (Hatcher et al., 2004) have been implicated in cell movement, the roles demonstrated for them are confined within the context of mesoderm. Still, these studies showed that in chimeras with neighbouring wild-type and T-box-deficient cells, the movement of wild-type cells in their normal developmental context resulted in the exclusion of T-box-deficient cells similar to what we demonstrate here. It would seem that this is a common phenomenon and may indicate a general functional mechanism for T-box proteins in cell migration during development.

Interestingly, overexpression of Tbx2b in the ectoderm led to the appearance of cells in the notochord, a mesodermal structure. Although it is known that Tbx2b is required for the specification of axial mesodermal structures at the expense of lateral mesodermal tissues (Dheen et al., 1999), what we demonstrate here is its ability to translocate cells from ectoderm to dorsal mesoderm. We do not yet know the precise mechanism of this phenomenon. However, we show here that a low level of Tbx2b is needed for proper cell adhesion and cell movement within the ectodermal sheet. It is possible that dorsal mesoderm has higher levels of cell adhesion, and the affected cells move into the underlying mesoderm during gastrulation. Analysis with maternal-zygotic one-eyed-pinhead (MZoep) mutant cells showed that internalization and mesendoderm formation in zebrafish can be attained autonomously by single cells (Carmany-Rampey and Schier, 2001). If so, it opens the possibility that differential activation of Tbx2b is a mechanism by which systematic differences in cell surface properties and cell segregation behaviour is modulated for the purpose of long-term effects on cell fate specification. More analysis is needed to better understand this observation.

The exclusion phenotype provided a rapid assay for screening signalling pathways that Tbx2b might be operating within. The screen suggests that Tbx2b functions within the context of Wnt signalling, specifically through the receptor Fz7. Zebrafish Fz7, like its homologue in Xenopus, has a broad range of functions from fate specification to cell movement, but it is the cell movement requirement for Fz7 that is mediated by Tbx2b. As Drosophila Omb also acts within the Wnt context in multiple developmental situations (Grimm and Pflugfelder, 1996), this developmental link may be conserved in evolution. Although Fz7 is shown to regulate tbx2b transcriptionally, a full analysis of the detailed molecular mechanism is beyond the scope of this study. Preliminary analysis of the 2.5 kb 5’ genomic sequence of tbx2b identified numerous Tcf-binding sites (not shown), hinting at the possibility of regulation of tbx2b transcription via β-catenin/Tcf.

The functional roles of the canonical and non-canonical Wnt pathways were thought to be quite different (Moon et al., 1997). In vertebrates, Wnt-dependent morphogenetic cell movements were linked to the non-canonical pathway (Tada et al., 2000; Heisenberg et al., 2000), which directly controls Ds-mediated cell polarity (Wallingford et al., 2000). The canonical Wnt pathway was associated with the initiation of CE movements, but not movement per se (Moon et al., 1997). Although β-catenin acts in both signalling and adhesion in insects and vertebrates (Moon et al., 2002), the involvement of the canonical Wnt pathway in cell movement has been shown only in invertebrates (Korswagen, 2002).

In the Xenopus blastula, β-catenin was proposed to regulate CE and mediate cell fate via two parallel pathways involving Nodal-related 3 and Siamois, respectively (Kuhl et al., 2001).
In zebrafish, β-catenin modulates Nodal signalling, to regulate both cell fate and cell movement (Myers et al., 2002); and Boz, to repress bmp2b (Leung et al., 2003). In this study, the ability of Fz7 to mediate Wnt signalling via the DX/DOM of Ds to effect cell adhesion and cell movement during gastrulation suggests that Ds may not function in a strictly modular manner. The current notion that cell movement events are mediated by the non-canonical pathway through the DEP- and PDZ-domains of Ds may need to be looked at afresh.

It has been shown recently that Tbx2 is required for patterning the atrioventricular canal and for morphogenesis of the outflow tract during heart development in mice (Harrelson et al., 2004). Cell migration plays an important role in heart formation in teleosts (Glickman and Yelon, 2002) and amniotes (Hatcher et al., 2004). Although tbx2b is expressed in the developing heart and the morphants display cardiac defects later in development (not shown), it remains to be seen if Tbx2b plays a role in the migration of cardiac cells.

Authors are indebted to members of V.K.’s laboratory, to W. Chia and to P. Singh for critical reading of this manuscript. We thank R. Moon, S. Vriz and U. Takeda for reagents and cDNA. We also thank W. Chia, S. H. Yang, E. Manser, D. Grunwald, C.-P. Heisenberg and D. Kimelman for discussion. We thank the anonymous reviewers for their invaluable comments that led to improvement of the manuscript. We apologise to many colleagues whose work was not referred to in this publication owing to space limitations. This work was supported by a research grant from the Agency for Science, Technology and Research of Singapore to V.K. Authors declare that they have no competing financial interests.
