Stem cell metabolism in tissue development and aging

Ng Shyh-Chang1,2,3, George Q. Daley1,2 and Lewis C. Cantley3,4,*

Summary
Recent advances in metabolomics and computational analysis have deepened our appreciation for the role of specific metabolic pathways in dictating cell fate. Once thought to be a mere consequence of the state of a cell, metabolism is now known to play a pivotal role in dictating whether a cell proliferates, differentiates or remains quiescent. Here, we review recent studies of metabolism in stem cells that have revealed a shift in the balance between glycolysis, mitochondrial oxidative phosphorylation and oxidative stress during the maturation of adult stem cells, and during the reprogramming of somatic cells to pluripotency. These insights promise to inform strategies for the directed differentiation of stem cells and to offer the potential for novel metabolic or pharmacological therapies to enhance regeneration and the treatment of degenerative disease.

Key words: Blastocyst metabolism, Pluripotent stem cells, Hematopoietic progenitors, Reprogramming, Metabolomics

Introduction
As the zygote develops into a multicellular organism, the evolving demands of rapid cell growth, tissue formation and organogenesis place drastically different metabolic requirements on embryos, early pluripotent stem cells, tissue-resident adult stem cells, transient amplifying tissue progenitors and, ultimately, mature adult tissues. During the 1960s and 1970s, advances in our understanding of the metabolism of embryos led to techniques for in vitro culture of blastocysts and the development of in vitro fertilization (IVF). More recently, advances in cancer cell metabolism have led to an explosion in our understanding of how aerobic glycolysis (the ‘Warburg effect’, see Glossary, Box 1), rather than normal glycolysis (see Glossary, Box 1) linked to the Krebs cycle (see Glossary, Box 1) and to oxidative phosphorylation (OxPhos, see Glossary, Box 1), supports rapid cellular growth. This understanding has led to new drug targets for cancer therapy. Within the past decade, studies of metabolism in various stem cell populations have also highlighted a role for cell-specific metabolic pathways that are modulated during differentiation or during reprogramming to pluripotency. These novel insights have challenged the long-held assumption that all metabolic enzymes perform the same housekeeping functions in all cells, and have provoked a resurgence of interest in metabolism. Overall, these results paint a picture of tissue- and cell-specific metabolic pathways and isoenzymes that are tightly regulated during development and perform unique functions in specific contexts. Such cell- and tissue-specific isoenzymes provide a therapeutic window for pharmacological manipulation. Hence, the application of metabolomics to the study of stem cells during development could lead to new breakthroughs in our understanding of embryogenesis and adult tissue homeostasis, with implications for ongoing efforts in stem cell biology, tissue regeneration and therapies for degenerative diseases.

In this Review, we outline the specific metabolic pathways that are active in mammalian totipotent stem cells (TSCs), in pluripotent stem cells before and after differentiation, in quiescent adult stem cells, and in proliferative stem/progenitor cells during mammalian tissue development. We also discuss the role of stemness factors in governing stem cell metabolism, and examine the role of stem cell metabolism during aging using insights gleaned from invertebrate models.

Metabolism in TSCs and the early (pre-blastocyst) embryo
Before the morula stage of development in preimplantation embryos, each individual early blastomere is totipotent (see Glossary, Box 1) and retains the ability to generate an entire organism and its placenta. Despite differences between mammalian species in the time spent in gestation, the amount of time required to develop to the blastocyst stage is remarkably conserved (Brinster, 1974). In the first week, blastomeres, which are considered here as TSCs in vitro, undergo a few self-renewing cell divisions and rounds of DNA replication, but the embryo as a whole experiences no net growth (Leese, 1995). TSCs likely autophagocytose their protein reserves, which drop by 26% by the eight-cell stage (Brinster, 1967).

Studies indicate that metabolism in TSCs is tightly controlled by the rate-limiting glycolysis enzymes hexokinase (HK) and phosphofructokinase 1 (PFK1), thus glycolysis rates are initially low (Fig. 1A) (Barbehenn et al., 1978). Instead, the only energy and carbon sources that TSCs can use are pyruvate analogs, a fact that is also true for primordial germ cells, oocytes and spermatocytes, which use pyruvate secreted by ovarian follicle cells and lactate secreted by testicular Sertoli cells. The advantages of this preference for pyruvate in TSCs remain unknown. Early embryo development is actually inhibited by high concentrations of glucose (Brinster and Troike, 1979). Only at the morula stage does the relative rate of glucose oxidation rival that of pyruvate (Leese and Barton, 1984). The oxidation of pyruvate in mitochondria then fuels the Krebs cycle, which in turn generates carbon intermediates and fuels OxPhos.

Despite the preference for pyruvate oxidation, the O2 consumption rate of TSCs is relatively low, comparable with that of adult skin or bone (Brinster and Troike, 1979). Consistent with the low O2 consumption rate, mitochondria are structurally immature in TSCs. Oocyte and TSC mitochondria are typically spherical elements at least 1 μm in diameter with few truncated

Anaplerosis. Reactions replenishing Krebs cycle intermediates that are shunted into other biosynthetic pathways.

Eicosanoids. Oxidized lipids derived from the oxidation of 20-carbon omega 3 or omega 6 essential fatty acids. There are four families of eicosanoids – prostaglandins, prostacyclins, thromboxanes and leukotrienes.

Fatty acid β-oxidation. A series of dehydrogenation, hydration, oxidation and thiolysis reactions that repeatedly cleave off the 2-carbon acetyl-CoA from fatty acids, which then feeds into the Krebs cycle.

Glucogenesis. Metabolic pathway that generates glucose from other carbon sources, such as pyruvate, lactate or glucogenic amino acids. It involves many glycolytic enzymes running in reverse.

Glycolysis. A metabolic pathway that breaks down one molecule of glucose into two molecules of pyruvate or lactate, generating ATP in the process. Glycolytic intermediates can also be shunted into anabolic pathways for biosynthesis, e.g. pentose phosphate, glycerol-3-phosphate, serine or glycine.

Krebs cycle. Cyclic series of condensation, isomerization, oxidation, decarboxylation and hydration reactions involving carboxylic acids in the mitochondria to generate energy through the oxidation of acetyl-CoA into CO2. In addition, the cycle provides precursors to generate certain amino acids, as well as NADH. Each complete turn of the cycle generates one GTP, two CO2, one FADH2 and three NADH molecules.

Mitochondrial membrane potential (ΔΨm). The voltage difference across the inner mitochondrial membrane that results from the proton gradient generated by proton pumps in the electron transport chain.

Oxidative phosphorylation (OxPhos). The mitochondrial reactions that generate and harness energy released from the oxidation of nutrients such as pyruvate, via a proton gradient, to synthesize ATP.

Pluripotent. Having the developmental potential to differentiate into any three germ layers – endoderm, mesoderm or ectoderm – that form the embryo proper.

Reactive oxygen species (ROS). Chemically reactive molecules containing oxygen, including superoxide and peroxide. ROS form as a by-product of OxPhos and irradiation, potentially causing damage to cell structures. Cumulatively, this is known as oxidative stress.

Toxipotent. Having the developmental potential to differentiate into all the cells in an organism, including any of the three germ layers – endoderm, mesoderm or ectoderm – as well as the extra-embryonic trophoblast, which forms the placenta in mammals.

Warburg effect. The observation that proliferative cancer or embryonic cells exhibit a high rate of glycolysis followed by lactate production, instead of a low rate of glycolysis followed by mitochondrial oxidation of pyruvate, despite high levels of O2. Also known as aerobic glycolysis.

The ATP generated by mitochondrial OxPhos is also used to actively transport ions into the early embryo. For example, the pH inside the early embryo is kept alkaline by importing high levels of bicarbonate from the oviduct and uterine fluid (Vishwakarma, 1962). Bicarbonate is important not just for pH buffering and mitochondrial replication, but it also contributes significantly to the carbon pool within TSCs (Graves and Biggers, 1970; Brinster, 1973). TSCs might use bicarbonate for carbon fixation via mitochondrial pyruvate carboxylase to generate oxaloacetate for anaplerosis (see Glossary, Box 1) or gluconeogenesis (see Glossary, Box 1), or via carbamoyl phosphate synthetase to generate nucleotides for DNA and RNA synthesis (Fig. 1D).
thought to shunt glycolytic intermediates into amino acid, lipid and nucleotide synthesis for cell proliferation (Vander Heiden et al., 2009). Similarly, mouse ESCs show increased activity in the pentose phosphate pathway (PPP, see Glossary, Box 1), which allows rapid nucleotide synthesis (Filosa et al., 2003; Manganelli et al., 2012; Varum et al., 2011). Thus, anabolic glycolysis is a common feature of metabolism in both ESCs and cancer cells.

Despite the low levels of OxPhos occurring in undifferentiated ESCs, O2 consumption is still important. However, ATP synthesis appears to be decoupled from O2 consumption, and depends on glycolysis instead (Fig. 2B) (Zhang et al., 2011a). Although the mechanism and reasons for this decoupling remain unclear, it is possible that ESCs consume O2 through the electron transport chain (ETC) to oxidize NADH into NAD+ and maintain the Krebs cycle flux. This might also allow ESCs to maintain an optimal redox potential for lipid synthesis from citrate and for amino acid synthesis from OAA or α-ketoglutarate (Shyh-Chang et al., 2011). In line with this, ESCs with high ΔΨm form teratomas more efficiently than ESCs with low ΔΨm (Schieke et al., 2008), and blastocysts deficient in mitochondrial oxidation enzymes, including the pyruvate dehydrogenase (PDH) complex, show developmental defects (Johnson et al., 1997; Johnson et al., 2001).

Mouse ESCs also use a unique mode of amino acid metabolism to maintain their pluripotent epigenetic state (Fig. 2C). In a screen for dependence on each of the 20 amino acids, restriction of Thr alone (and to a lesser extent, Met or Cys) uniquely abolished mouse ESC growth. By contrast, other proliferative cell lines such as HeLa, 3T3 or mouse embryonic fibroblasts were sensitive to restriction of other amino acids but not to Thr restriction (Wang et al., 2009). Consistent with these findings, expression of the Thr-
catabolizing enzyme threonine dehydrogenase (TDH) is dramatically upregulated in early blastocysts and ESCs (and after iPSC reprogramming), relative to differentiated cells (Wang et al., 2009; Shyh-Chang et al., 2013). TDH is a mitochondrial enzyme that controls the the rate-limiting step in the metabolism of Thr into Gly and acetyl-CoA. Gly can be subsequently used by the mitochondrial enzyme glycine decarboxylase (GLDC) to generate 1-carbon equivalents for the folate pool. Like TDH, GLDC is also upregulated in pluripotent cells relative to differentiated cells (Shyh-Chang et al., 2013). Furthermore, pharmacological inhibition or knockdown of TDH disrupts mouse ESC colony growth (Alexander et al., 2011; Shyh-Chang et al., 2013). Collectively, these findings suggest that the metabolites generated by Thr degradation may be used specifically for the self-renewal of pluripotent ESCs. Indeed, it has recently been demonstrated that TDH and GLDC regulate the synthesis of 5-methylltetrahydrofolate, thereby modulating S-adenosylmethionine (SAM) metabolism and histone H3K4 tri-methylation (Shyh-Chang et al., 2013) (Box 2). H3K4 tri-methylation is associated with open euchromatin, which is crucial for the epigenetic plasticity of pluripotent ESCs and their self-renewal (Azuara et al., 2006; Gaspar-Maia et al., 2011; Ang et al., 2011). TDH regulation of the folate pool was also found to promote rapid proliferation in mouse ESCs (Wang et al., 2009), consistent with findings that GLDC regulates the folate pool to promote nucleotide synthesis and rapid proliferation in cancer stem cells (Zhang et al., 2012).

**Metabolism in differentiating ESCs**

When ESCs differentiate, glycolytic flux decreases dramatically (Fig. 3A,B). Thr-Gly metabolism is extinguished and mitochondrial OxPhos fueled by glucose and fatty acids increases (Fig. 3C,D) (Cho et al., 2006; Chung et al., 2007; Facucho-Oliveira et al., 2007; Wang et al., 2009). Thus, cells acquire an even more oxidized state. Furthermore, pluripotent ESCs are enriched with unsaturated lipids such as omega 3 and omega 6 fatty acids that contain readily oxidizable carbon-carbon double bonds (Yanes et al., 2010). These unsaturated lipids prime ESCs to differentiate after oxidation by reactive oxygen species (ROS, see Glossary, Box 1) to form eicosanoids (Fig. 3E). In support of this concept, pharmacological inhibition of enzymes in the eicosanoid synthesis pathway (see Glossary, Box 1), which oxidizes these unsaturated lipids, preserves ESC pluripotency (Yanes et al., 2010).

**Metabolism in quiescent adult stem cells**

Unlike proliferative ESCs, most adult stem cells are quiescent. Such quiescent adult stem cells reside in various tissues and include long-term hematopoietic stem cells (LT-HSCs) and mesenchymal stem cells (MSCs) in the bone marrow, neural stem cells (NSCs) in the brain, epidermal stem cells in the hair follicle bulge, and satellite cells in skeletal muscles. It is thought that quiescent adult stem cells generally maintain a slow-cycling state to avoid cellular damage from ROS and to ensure life-long tissue renewal capacity (Rossi et al., 2008; Suda et al., 2011). But is the metabolic program in adult stem cells intrinsically required for stem cell self-renewal or is it an adaptive response to the often hypoxic environment?

It is known, for instance, that adult LT-HSCs prefer to use glycolysis (Fig. 4A), a phenotype that some have argued to be an adaptation to the hypoxic environment of the bone marrow niche (Suda et al., 2011). One potential advantage of hypoxia-induced glycolysis in LT-HSCs is the associated reduction in ROS production from mitochondria. LT-HSCs are sensitive to ROS, and they either undergo differentiation or apoptosis in the presence of excessive ROS when the stress response is defective (Tothova et al., 2007). NSCs in the hypoxic brain exhibit similar responses to ROS (Renault et al., 2009). This suggests, however, that glycolysis is not simply an environmental adaptation but an intrinsic necessity for quiescent adult stem cells. In line with this, the pro-glycolytic phenotype of LT-HSCs appears to be programmed by the HSC transcription factor MEIS1 via its target hypoxia-inducible factor 1α (HIF1α) (Simsek et al., 2010), which upregulates many glycolytic enzymes. Similar to embryonic TSCs and ESCs, adult HSCs possess low mitochondrial mass and immature mitochondrial morphology (Chung et al., 2007). In fact, the majority of LT-HSCs can be metabolically sorted by gating for low ΔΨm and low endogenous NADH, and the resultant cells have greater hematopoietic capacity in vivo (Simsek et al., 2010). The low ΔΨm could be partly because LT-HSCs express higher levels of the pyruvate dehydrogenase kinases PDK1 and PDK3, which inhibit PDH and mitochondrial pyruvate oxidation (Fig. 4B) (Klimmeck et al., 2012). Interestingly, another pair of PDKs regulated by HIF1α, PDK2 and PDK4, are also required by LT-HSCs, demonstrating that PDK-regulated OxPhos generally acts as a
switch for LT-HSC function (Takubo et al., 2013). Overall, it appears that OxPhos capacity is reduced in LT-HSCs. However, peroxisome proliferator activator receptor δ-driven fatty acid β-oxidation (see Glossary, Box 1) has been shown to promote LT-HSC self-renewal (Fig. 4C) (Ito et al., 2012), suggesting that it is not the absolute quantity per se, but the efficiency of OxPhos that might also be important.

MSCs also reside in hypoxic environments in vivo. Relative to the more differentiated osteoblasts within the bone marrow, MSCs express higher levels of glycolytic enzymes and lower levels of OxPhos proteins, suggesting that MSCs rely more on glycolysis than do osteoblasts (Chen et al., 2008a). Nevertheless, MSCs expanded under normoxia can still use OxPhos with a high O2 consumption rate, suggesting that glycolysis may be an environmental adaptation for MSCs (Pattappa et al., 2011). In fact, MSC proliferative and colony formation capacity is significantly increased in normoxia (Pattappa et al., 2013). The switch to OxPhos comes at a cost, however, as MSCs expanded under normoxia show a three- to fourfold increase in senescence, suggesting that hypoxia-induced glycolysis limits MSC proliferation to prevent oxidative stress-induced senescence and preserve MSC long-term self-renewal (Pattappa et al., 2013). Thus, in at least three types of adult stem cells, namely LT-HSCs (Tothova et al., 2007), MSCs (Chen et al., 2008a) and NSCs (Renault et al., 2009), the induction of ROS forces adult stem cells out of quiescence in hypoxia, and into a more proliferative state in normoxia. This may be a common mechanism for priming stem cell differentiation.

**Fig. 3. Metabolism in differentiating embryonic stem cells.** (A) Glycolytic flux and lactate production drop rapidly upon embryonic stem cell differentiation. (B) Flux into the pentose phosphate pathway (PPP) decreases as a result. (C) O2 consumption increases sharply as the electron transport chain (ETC) again becomes coupled to ATP synthase to fulfill the needs of cell differentiation. (D) Glycolysis also becomes more coupled to the Krebs cycle, as pyruvate is transported more efficiently into mitochondria. (E) Increased ETC activity leads to increased reactive oxygen species (ROS) and eicosanoid signaling, which promote cell differentiation. Ac-CoA, acetyl coenzyme A; HK, hexokinase; F6P, fructose-6-phosphate; FBP, fructose-1,6-bisphosphate; G6P, glucose-6-phosphate; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; LDHA, lactate dehydrogenase A; OAA, oxaloacetate; Ox Phos, oxidative phosphorylation; PDH, pyruvate dehydrogenase complex; PFK1, phosphofructokinase 1; TPI, triosephosphate isomerase.

**Fig. 4. Metabolism in quiescent long-term hematopoietic stem cells.** (A) The hematopoietic stem cell (HSC) transcription factor MEIS1 and low O2 levels combine to activate hypoxia-inducible factor 1α (HIF1α) activity, which in turn promotes glycolysis in quiescent long-term HSCs (LT-HSCs). (B) HIF1α-dependent pyruvate dehydrogenase kinases (PDK1-4) prevent pyruvate oxidation by suppressing pyruvate dehydrogenase complex (PDKH). (C) Peroxisome proliferator activator receptor δ (PPARδ)-driven fatty acid oxidation in the mitochondria is required for LT-HSC self-renewal and quiescence. Inhibition of fatty acid oxidation leads to LT-HSC proliferation and differentiation. Ac-CoA, acetyl coenzyme A; ETC, electron transport chain; F6P, fructose-6-phosphate; FBP, fructose-1,6-bisphosphate; G6P, glucose-6-phosphate; HK1, hexokinase 1; LDHA, lactate dehydrogenase A/B; PGK, phosphoglycerate kinase; PK, pyruvate kinase.
Metabolism in proliferative adult stem/progenitor cells

In addition to long-lived quiescent stem cells, a number of adult tissues contain proliferative stem and progenitor cells that contribute to tissue homeostasis and renewal. These include hematopoietic progenitors, neural progenitors, mesenchymal progenitors, skeletal myoblasts, cardiomyocyte progenitors, intestinal stem cells (ISCs) and germline stem cells (GSCs). As we discuss below, these are all highly proliferative undifferentiated cells that rely on different combinations of glycolysis and OxPhos for proliferation (summarized in Table 1).

Hematopoietic progenitors

The metabolic switch from anaerobic glycolysis under hypoxia for quiescent adult stem cells, to a mixture of aerobic glycolysis and OxPhos for proliferative adult stem/progenitor cells is well exemplified in hematopoiesis. A proteomics study of the transition from HSCs to myeloid progenitors showed that among the hexokinase isoforms, HK1 expression is higher in HSCs, whereas HK2 and HK3 expression levels are higher in myeloid progenitors (Klimmeck et al., 2012). HK1 is primarily associated with catabolism, whereas HK2 and HK3 have anabolic roles (Wilson, 2003), suggesting that HSCs rely on glycolysis for energy, whereas myeloid progenitors use glycolysis for anabolic growth (Fig. 5A).

In fact, myeloid cells express high levels of the transcription factor PU.1, which transactivates HK3 to drive myeloid differentiation and maintain myeloid identity (Federzoni et al., 2012). Myeloid progenitors also express lower levels of PDKs, suggesting that PDK-mediated suppression of OxPhos in HSCs is relieved upon myeloid commitment (Klimmeck et al., 2012; Takubo et al., 2013). In addition, the mitochondrial phosphatase PTPMT1, which dephosphorylates phosphatidylglycerol phosphate during cardiolipin synthesis (Zhang et al., 2011b), appears to be another master regulator of the OxPhos switch (Fig. 5B) (Yu et al., 2013).

Concomitant with the increase in OxPhos activity as HSCs differentiate, ROS levels also increase (Fig. 5B) (Tothova et al., 2013).

Hematoapoietic progenitors

The metabolic switch from anaerobic glycolysis under hypoxia for quiescent adult stem cells, to a mixture of aerobic glycolysis and OxPhos for proliferative adult stem/progenitor cells is well exemplified in hematopoiesis. A proteomics study of the transition from HSCs to myeloid progenitors showed that among the hexokinase isoforms, HK1 expression is higher in HSCs, whereas HK2 and HK3 expression levels are higher in myeloid progenitors (Klimmeck et al., 2012). HK1 is primarily associated with catabolism, whereas HK2 and HK3 have anabolic roles (Wilson, 2003), suggesting that HSCs rely on glycolysis for energy, whereas myeloid progenitors use glycolysis for anabolic growth (Fig. 5A).

In fact, myeloid cells express high levels of the transcription factor PU.1, which transactivates HK3 to drive myeloid differentiation and maintain myeloid identity (Federzoni et al., 2012). Myeloid progenitors also express lower levels of PDKs, suggesting that PDK-mediated suppression of OxPhos in HSCs is relieved upon myeloid commitment (Klimmeck et al., 2012; Takubo et al., 2013). In addition, the mitochondrial phosphatase PTPMT1, which dephosphorylates phosphatidylglycerol phosphate during cardiolipin synthesis (Zhang et al., 2011b), appears to be another master regulator of the OxPhos switch (Fig. 5B) (Yu et al., 2013).

Concomitant with the increase in OxPhos activity as HSCs differentiate, ROS levels also increase (Fig. 5B) (Tothova et al., 2013).

OxPhos, oxidative phosphorylation; PPP, pentose phosphate pathway; ROS, reactive oxygen species.
In the Drosophila larval lymph gland, hematopoietic cells resembling mammalian myeloid progenitors require ROS to differentiate into mature blood cells (Owusu-Ansah and Banerjee, 2009). The targets of ROS that prime HSC differentiation still remain unknown, but it is possible that components of the eicosanoid biosynthesis pathway, which oxidizes lipids in ESCs (Yanes et al., 2010), may be involved. In fact, the eicosanoid product prostaglandin E2 has been shown to significantly enhance HSC proliferation, hematopoietic colony formation and hematopoiesis in vivo by activating Wnt signaling (Goessling et al., 2009), suggesting that eicosanoids might be important for HSC proliferation and differentiation.

**Neural progenitors**

Like hematopoietic progenitors, proliferative neural progenitors show high levels of glycolysis mediated by HK2 (Gershon et al., 2013); and like hematopoietic progenitors, the directed differentiation of ESCs into neural progenitors is stimulated by the eicosanoid pathway and also by fatty acid metabolism (Yanes et al., 2010). However, it is unclear whether these effects of fatty acids are due to mitochondrial fatty acid \(\beta\)-oxidation or fatty acid use in lipogenesis, or both. The oxidative stress response mediated by FOXO3 becomes rapidly deactivated upon NSC differentiation, suggesting that mitochondrial oxidation-induced ROS is required in neural progenitors (Fig. 6A) (Renault et al., 2009). In fact, deficiency in FOXO3 causes depletion of adult brain NSCs and an expansion of oligodendrocytes in the corpus callosum (Renault et al., 2009). However, neural progenitors require lipogenesis, which is mediated by fatty acid synthase and acetyl-CoA carboxylase (ACC), for lipid membrane synthesis and for neural progenitor proliferation (Knobloch et al., 2013). These results suggest that both fatty acid synthesis and oxidation-induced ROS might be crucial for neural progenitors (Fig. 6B). Alternatively, it is possible that fatty acid \(\beta\)-oxidation is only required in quiescent NSCs, resembling the situation observed in LT-HSCs (Ito et al., 2012). Upon differentiation into neural progenitors, the ACC-mediated increase in malonyl-CoA could then allosterically inhibit fatty acid \(\beta\)-oxidation and promote fatty acid synthesis. Yet another possibility is that fatty acid-derived lipids are oxidized via the eicosanoid pathway to promote neurogenesis. More work is required to resolve these issues.

**Mesenchymal progenitors**

During adipogenesis, mesenchymal pre-adipocytes activate a lipogenic program involving ATP citrate lyase (ACL) to increase glucose metabolism and to synthesize lipids for fat storage (Fig. 7A,B). Adipocytes also rely upon ACL to increase their supply of acetyl-CoA for increased histone acetylation during adipogenesis (Fig. 7B,C). This is necessary for transactivation of key metabolic proteins such as the glucose transporter GLUT4, HK2, PFK1, LDHA and the carbohydrate-responsive element-binding protein (ChREBP) in the lipogenic program (Wellen et al., 2009). Directed adipogenesis of MSCs also increases mammalian target of rapamycin complex 1 (mTORC1)-dependent mitochondrial biogenesis, OxPhos and ROS (Fig. 7B). Endogenous ROS generated from the mitochondrial ETC complex III is required to initiate adipogenesis, suggesting that OxPhos and ROS are not simply a consequence of adipogenesis but are a causal factor in promoting it (Tormos et al., 2011). Similarly, directed osteogenesis of MSCs leads to an increase in mitochondrial biogenesis and OxPhos in osteoblasts (Chen et al., 2008a). Unlike adipogenesis, however, osteogenesis cannot tolerate ROS (Fig. 7D). In fact, antioxidant enzymes such as superoxide dismutase and catalase are simultaneously upregulated with OxPhos in osteoblasts to prevent ROS accumulation (Chen et al., 2008a). In contrast to adipogenesis and osteogenesis, MSCs undergoing chondrogenesis have significantly reduced O2 consumption and OxPhos, indicating a shift towards increased glycolysis (Fig. 7E) (Pattappa et al., 2011). Furthermore, hypoxia inhibits MSC osteogenesis, whereas chondrogenesis is unaffected (Pattappa et al., 2013). Taken together, these studies demonstrate that careful manipulation of oxidative metabolism can direct the differentiation of MSCs either into adipocytes, osteoblasts or chondroblasts.

**Skeletal myoblasts**

Myogenesis during muscle regeneration is mediated by the proliferation of myoblasts derived from satellite cells, which undergo fusion to form myotubes. The expression of glucose transporters is tightly regulated during this process. GLUT1, for example, is expressed specifically in satellite cells and myoblasts (Fig. 8A). Levels of the higher-affinity transporter GLUT3 increase markedly in myoblasts during myogenesis, and decrease in myotubes. By contrast, the high-affinity and insulin-sensitive GLUT4 is expressed specifically in myotubes (Fig. 8B). Accordingly, the rate of glucose transport rises significantly during myogenesis, suggesting a switch in glucose metabolism during this process (Guillet-Deniau et al., 1994). This switch is supported by findings that myoblast differentiation leads to a dramatic switch in the expression of pyruvate kinase isoforms, mediated by RNA-binding proteins, from the pro-glycolytic PKM2 (pyruvate kinase, muscle isoform 2) to the pro-OxPhos PKM1 (Fig. 8A,B) (Clower et al., 2010; David et al., 2010). In fact, myoblasts require glycolytic phosphoglycerate kinase 1 (PGK1) for self-renewal (Bracha et al., 2010). Hexose-6-phosphate dehydrogenase (H6PD) in the pentose phosphate pathway (PPP), and ACL-driven acetyl-CoA synthesis also appear to be required for myoblast self-renewal in vitro (Bracha et al., 2010).

**Cardiomyocyte progenitors**

In the fetal heart, cardiomyocyte progenitors prefer to use lactate to fuel OxPhos (Werner and Sicard, 1987). Knowledge of these metabolic features has aided the efficient derivation of cardiomyocytes from ESCs and iPSCs during directed differentiation.
Metabolism and ‘stemness’ factors: establishing a link

After decades of research in stem cell biology, candidate factors that define ‘stemness’ across the myriad of tissue lineages and stem cells are emerging. One outstanding issue in stem cell biology is whether such a stemness factor, if it exists, drives specific cellular functions such as metabolism in a specific manner to maintain stemness. One such candidate factor is LIN28, an RNA-binding protein first identified in C. elegans through mutagenesis screens for regulators of developmental timing, or heterochrony (Ambros and Horvitz, 1984; Shyh-Chang and Daley, 2013). In mammals, LIN28A/B have been found to be regulators of pluripotent ESCs and iPSCs, fetal HSCs, neural crest progenitors, skeletal myoblasts during muscle regeneration and spermatogonia (Viswanathan et al., 2013). These results demonstrate how understanding stem cell metabolism can lead to effective strategies for directed differentiation and mass production of functional cells and tissues.

Stem cell metabolism and aging

Several lines of evidence support the notion that enhanced tissue regeneration by adult stem cells can delay aging, whereas a decline in adult stem cell numbers and function drives aging-related syndromes (Sahin and Depinho, 2010). Accumulating damage from ROS, for example, can compromise stem cell self-renewal and promote aging (Rossi et al., 2008; Sahin and Depinho, 2010). Nutrient-sensitive signaling pathways that regulate organismal aging, such as the insulin-PI3K, Akt-FOXO, mTOR and AMPK pathways, also regulate the balance between quiescence and proliferation of stem cells during aging (Chen et al., 2009; Jasper and Jones, 2010; Kharas et al., 2010; Kalaitzidis et al., 2012; Magee et al., 2012). As one example of the crosstalk between nutrient-sensitive signaling and ROS in mammals, deficiency in the FOXO transcription factors dampens the oxidative stress response and depletes mouse LT-HSCs (Tothova et al., 2007). Likewise, deletion of the AMPK regulator LKB1 (serine/threonine protein kinase 11) leads to loss of mouse LT-HSC quiescence, depletion of LT-HSC pools and impaired hematopoiesis, probably owing to mitochondrial defects (Gan et al., 2010; Gurumurthy et al., 2010; Nakada et al., 2010). The mTOR signaling pathway also plays a major role in governing stem cell fate. For example, deletion of the metabolic sensor TSC1 (tuberous sclerosis 1), which upregulates mTORC1 signaling, drives mouse LT-HSCs into proliferation due to increased mitochondrial biogenesis, ultimately depleting the LT-HSCs and impairing hematopoiesis (Chen et al., 2008b). Consistently, mTORC1 inhibition with rapamycin delays mouse LT-HSC aging by preserving adult LT-HSC self-renewal and hematopoietic capacity (Chen et al., 2009). Excessive mTOR signaling also leads to adult epidermal stem cell exhaustion and progressive hair loss in mice — a phenotype that rapamycin can delay (Castillo et al., 2009). Perhaps more strikingly, rapamycin treatment late in adulthood can extend organismal longevity in mice (Harrison et al., 2009). These mechanisms appear to be well-conserved in Drosophila too, as insulin-Pi3K signaling also regulates the proliferative capacity of Drosophila hematopoietic progenitors (Shim et al., 2012), neuroblasts (Chell and Brand, 2010; Sousa-Nunes et al., 2011), intestinal stem cells (ISCs) (Biteau et al., 2010; Choi et al., 2011; O’Brien et al., 2011) and germ line stem cells (GSCs) (McLeod et al., 2010). Thus, metabolic signaling pathways that regulate aging might do so via
stem cell metabolism, by acting as nutrient sensors that modulate regenerative capacity during aging (Fig. 5C).

Drosophila models of ISCs provide strong evidence that efficient oxidative metabolism can enhance stem cell self-renewal during aging and contribute to organismal longevity. One example is the demonstration that intestine-specific upregulation of the Drosophila PGC1 homolog Spargel, a master regulator of mitochondrial biogenesis, can delay ISC aging and the consequent accumulation of mis-differentiated cells during aging by enhancing the efficiency of OxPhos. Moreover, Spargel upregulation in ISCs improves intestinal integrity and extends adult organismal longevity in old flies (Rera et al., 2011). In the same vein, it is well known that redox balance regulates ISC proliferation. In the Drosophila intestine, high levels of ROS are produced by enterocytes to control bacterial populations. ISCs respond to this oxidative stress by proliferating as part of a regenerative response. But over time this can lead to hyperproliferation, stem cell exhaustion and epithelial degeneration in the aging animal. In fact, ROS-induced hyperproliferation can be prevented with antioxidants (Hochmuth et al., 2011). Moreover, organismal longevity can be increased upon gain-of-function of nuclear factor erythroid 2-related factor 2 (NRF2) or its C. elegans homolog SKN1, master regulators of the oxidative stress response (Hochmuth et al., 2011). By contrast, tissue-specific loss of NRF2 in ISCs causes accumulation of ROS and accelerates aging-related degeneration of the intestine (Hochmuth et al., 2011). Interestingly, loss of the NRF2 regulator kelch-like ECH-associated protein 1 (KEAP1) leads to hyperkeratosis in the gastrointestinal tract in mice (Wakabayashi et al., 2003), suggesting that NRF2 might also control ISC proliferation and aging in mammals.

Although very little is known regarding GSC metabolism, GSC proliferation is known to be regulated by the availability of various nutrients. GSCs in the Drosophila ovary adjust their proliferation rates to nutritional conditions (Drummond-Barbosa and Spradling, 2001), and the nutrient-sensitive insulin/IGF1 and TOR signaling pathways are required for this response (LaFever and Drummond-Barbosa, 2005; Hsu et al., 2008; Ueishi et al., 2009; LaFever et al., 2010). Given that studies in C. elegans have shown that GSCs can regulate C. elegans longevity (Arantes-Oliveira et al., 2002; Wang et al., 2008), it will be interesting to see whether GSC metabolism plays a role in regulating C. elegans and mammalian longevity.

Calorie restriction might also promote longevity in part by promoting the self-renewal of stem cells. Calorie restriction not only extends longevity but also prolongs the health of organisms, ranging from worms and flies to rodents and primates, by improving metabolic homeostasis and decreasing the incidence of degenerative diseases and cancer (Barger et al., 2003). However, the detailed mechanisms underlying the benefits of calorie restriction in specific tissues has remained unclear until recently. In Drosophila, calorie restriction conditions that extend longevity also delay the loss of male GSCs over the course of aging (Mair et al., 2010). In mammalian muscles, calorie restriction boosts the number and myogenic function of skeletal satellite cells, by increasing mitochondrial biogenesis and enhancing OxPhos (Cerletti et al., 2012). In fact, the pro-myogenic effect of calorie restriction can be recapitulated in vitro by replacing glucose in satellite cell media with galactose to force the use of fatty acid oxidation and OxPhos. In the intestinal villus crypts, calorie restriction leads to upregulation of cyclic ADP-ribose (cADPR) signaling in the intestinal niche Paneth cells by inhibiting mTOR signaling. As a result, cADPR signaling induces the proliferation of leucine rich repeat-containing G protein-coupled receptor 5 (LRG5)-positive ISCs during calorie restriction (Yilmaz et al., 2012). Thus, calorie restriction can lead to complex effects in niche and stem cells to promote stem cell function and counteract aging-related degeneration.

Conclusions

By the end of the 20th century, early seminal discoveries of metabolism in early embryos led to the perfection of techniques in blastocyst culture and IVF. More recent insights into the metabolism in human ESCs have also led to rapid advances in chemically defined conditions for human ESC culture, iPSC reprogramming and their use in human disease models. As we move forwards, a deeper understanding of human stem and progenitor cell metabolism could lead to similar breakthroughs in our efforts to define conditions to culture functional human tissues in vitro via directed differentiation of human ESCs. Furthermore, it is clear that our understanding of stem cell metabolism could also be useful in fighting aging-related degeneration in patients. Studies of metabolism in stem cells thus harbor enormous potential for the field of regenerative medicine. One recent example is the large production of functional human cardiomyocytes from human ESCs achieved by changing the primary carbon source in growth media from glucose to lactate (Toyohara et al., 2013), thus yielding a source of cells that could help treat degenerative heart diseases in the future. But progress is slow elsewhere. Much remains unclear about metabolism in quiescent adult stem cells. This gap in our knowledge represents a crucial barrier in our ability to grow, study and use adult stem cells ex vivo, and to derive transplantable adult stem cells from human ESCs. A case in point is that highly desired methods for long-term culture and expansion of LT-HSCs do not yet exist. Similarly, much remains unknown about the metabolic requirements of various adult progenitor cells and their differentiated progeny, such that we are still unable to differentiate properly many adult stem and progenitor cells into fully functional, terminally differentiated cells that we can grow or maintain in vitro.

Fig. 8. Metabolism in skeletal myoblasts and myotubes. (A) Myoblasts use GLUT1 and GLUT3 for glucose uptake. Glycolysis mediated by phosphoglycerate kinase 1 (PGK1) is necessary for myoblast self-renewal. The low activity pyruvate kinase isoform M2 (PKM2) then facilitates accumulation of glycolytic intermediates for anabolic metabolism in myoblasts. For example, the pentose phosphate pathway (PPP), which is mediated by hexose-6-phosphate dehydrogenase (H6PD), shunts glucose-6-phosphate (G6P) into ribose and NADPH synthesis. ATP citrate lyase (ACL), which generates acetyl-CoA (Ac-CoA) from citrate, is also necessary for myoblast self-renewal. (B) Upon cell fusion and differentiation into myotubes, glucose uptake and glycolysis are increased by GLUT4, which is sensitive to regulation by insulin-PI3K-Akt signaling. Mitochondrial oxidative phosphorylation (OxPhos) also increases, partly owing to the switch to the high activity pyruvate kinase isozyme M1 (PKM1).
(Lyssiotis et al., 2011; Lairson et al., 2013). Although the traditional focus in this regard has been on growth factors and transcription factors, it would also be crucial to discover the necessary metabolic conditions. In fact, optimal metabolic conditions need not only be permissive for the directed differentiation of cells, but could also serve as instructive regulatory signals (see Box 2). Drugs could even be developed to manipulate pharmacologically the relevant enzymes, which have historically proven to be one of the most druggable classes of proteins in humans.

To achieve these goals, further advances in metabolomic technologies might be necessary. Much of the extant literature on stem cell metabolism is based on steady-state measurements of lysed cells. Given the rapid kinetics of metabolic reactions, it will be crucial to measure metabolic fluxes inside cells. Isotope-tracing methods in gas or liquid chromatography mass spectrometry (GC-MS or LC-MS) are state-of-the-art techniques in this area with their high levels of sensitivity, but still suffer from the inability to track real-time changes in vivo. Nuclear magnetic resonance (NMR) imaging methods could potentially overcome this barrier, but they currently show poorer sensitivity compared with mass spectrometry.

Another important barrier to advances in stem cell metabolism is the current lack of reliable methods for metabolomic profiling at the single-cell level. Current methods are limited to single fluorescent reporters of a few metabolic indicators, such as the ATP/AMP ratio, the NADH/NAD ratio or ROS abundance, instead of the hundreds of metabolites measurable by metabolomics. In addition, the intercellular metabolism and subcellular metabolism of stem cell niches in vivo also await further exploration. Therefore, we emphasize the need to explore beyond the current paradigm of in vitro stem cell metabolism to one that also encompasses the real-time changing metabolic needs of stem cells in vivo.

Another tradition among extant metabolic studies is the focus on the carbon and energy source of cells. This focus has led to numerous studies on key common pathways in glucose metabolism, i.e. glycolysis, OXPhos and ROS. However, insufficient attention has been dedicated to amino acid and lipid metabolism. Recent studies are just beginning to show that Thr-Gly metabolism is important to the folate pool and SAM/Met metabolism, with implications for nucleotide synthesis during proliferation and histone methylation for epigenetic regulation in stem cells. Acetyl-CoA metabolism is also beginning to emerge as a major regulator of protein (including histone) acetylation to regulate stem cells epigenetically. Furthermore, lipogenesis is emerging as a key pathway that sustains membrane synthesis and proliferation, whereas lipid oxidation via the eicosanoid pathway might generate a diversity of tissue-specific signaling molecules necessary to guide stem cell differentiation. An entire universe of cell- or tissue-specific metabolic pathways might be awaiting future discovery – with the potential to revolutionize regenerative medicine.
