Multiple cell and population-level interactions with mouse embryonic stem cell heterogeneity

Danielle Cannon¹, Adam M. Corrigan¹, Agnes Miermont¹, Patrick McDonel² and Jonathan R. Chubb¹,*

ABSTRACT
Much of development and disease concerns the generation of gene expression differences between related cells sharing similar niches. However, most analyses of gene expression only assess population and time-averaged levels of steady-state transcription. The mechanisms driving differentiation are buried within snapshots of the average cell, lacking dynamic information and the diverse regulatory history experienced by individual cells. Here, we use a quantitative imaging platform with large time series data sets to determine the regulation of developmental gene expression by cell cycle, lineage, motility and environment. We apply this technology to the regulation of the pluripotency gene Nanog in mouse embryonic stem cells. Our data reveal the diversity of cell and population-level interactions with Nanog dynamics and heterogeneity, and how this regulation responds to triggers of pluripotency. Cell cycles are highly heterogeneous and cycle time increases with Nanog reporter expression, with longer, more variable cycle times as cells approach ground-state pluripotency. Nanog reporter expression is highly stable over multiple cell generations, with fluctuations within cycles confined by an attractor state. Modelling reveals an environmental component to expression stability, in addition to any cell-autonomous behaviour, and we identify interactions of cell density with both cycle behaviour and Nanog, Rex1 expression dynamics showed shared and distinct regulatory effects. Overall, our observations of multiple partially overlapping dynamic heterogeneities imply complex cell and environmental regulation of pluripotent cell behaviour, and suggest simple deterministic views of stem cell states are inappropriate.

INTRODUCTION
Spatial and temporal accuracy of gene expression programmes is central to cell choices during differentiation. As cells grow and divide, they dilute and turnover their contents and are exposed to intrinsic and extrinsic sources of stochasticity. For cells to differentiate, gene expression programmes must be resistant to these effects, yet reliably integrate appropriate autonomous and external signals. In recent decades, predominant approaches to investigate cell choices have been molecular, with mechanistic understanding emerging from insight into regulation, molecular interactions and effects of specific regulators. Gene regulation by higher scales of organisation – cells and tissues – has been comparatively neglected, with data largely taken from ensemble measures of gene expression from dead cells. These methods lose cell context and cell diversity and cannot monitor the emergence and maintenance of gene expression differences between cells. However, advancements in live imaging and image analysis technologies now permit a more detailed investigation into these different levels of regulation.

To study the dynamics of gene expression states in cell lineages, we investigate the heterogeneity in pluripotency factor expression in mouse embryonic stem cells (mESCs). Expression of proteins such as Nanog, Rex1 (Zfp42) and Stella (Dppa3) is highly heterogeneous in mESCs (Chambers et al., 2007; Hayashi et al., 2008; Toyooka et al., 2008). For Nanog, expression is bimodal, with high and low local maxima (Chambers et al., 2007). Nanog expression relates to phenotypic behaviour, with low-expressing cells showing a tendency to differentiate and high-expressing cells tending towards self-renewal (Chambers et al., 2007; Abranches et al., 2014). Treatment of ESCs with 2i inhibitors (Ying et al., 2008) favours self-renewal, and shifts Nanog expression towards a unimodal high distribution. In culture containing serum and LIF, cells can fluctuate between high and low states (Chambers et al., 2007; Kalmar et al., 2009; Miyarai and Torres-Padilla, 2012; Abranches et al., 2014; Singer et al., 2014) making it a potentially excellent culture system for understanding the mechanisms of how gene expression differences arise between cells. Despite several studies on ‘spontaneous’ fluctuations of Nanog, triggers for the spontaneous switching are not known, necessitating a more comprehensive investigation of the regulatory influences governing expression.

We propose that key regulation of pluripotency factor expression will be identifiable in the dynamic behaviour of cells and their niche. Cell cycle dynamics are intimately associated with cell fate choice in many systems (Budinhardt and Gonczy, 2009). Is ESC cell cycle behaviour a determinant of gene expression? In mESCs, treatments prolonging cell cycles do not perceptibly alter the expression of pluripotency genes such as Nanog (Li et al., 2012; Li and Kirschner, 2014). However, although early embryonic cell cycles can be highly synchronous, many eukaryotic cycles are highly heterogeneous (Brooks, 1981; Di Talia et al., 2007; Muramoto and Chubb, 2008) and, with different signalling pathways operating at different cycle stages, cycle variability potentially provides a driver of gene expression heterogeneity. The heterogeneity of the ESC cycle has not been determined. Other sources of heterogeneity come from cell history and environment. How does past behaviour of a cell influence future gene expression choices? Different cells have different neighbours and so potentially experience different signals and mechanical triggers. Standard mixing or static measurements of gene expression do not register dynamic cell properties such as cell cycle behaviour, cell history and environmental dynamics, and perturbation experiments often
confound analysis due to the complexity of molecular interactions regulating most cellular processes.

To determine the contributions of cell and population-level processes to pluripotency factor gene expression, we investigated the regulation of Nanog expression using high-content imaging of multiple generations of unperturbed mESCs. Our large-scale data approach reveals the complexity of interactions underlying Nanog expression dynamics. We identify interactions between Nanog reporter expression, cell cycle and cell density, and reveal how expression is confined into an attractor state. We address how coupling between cellular processes is modulated during the transition to the pluripotent ground state. Finally, we introduce a new technique to distinguish cell-autonomous and non-autonomous regulation of cellular choices without experimental perturbation. Our approaches are generally applicable to understanding the regulation of gene expression decisions and cell behaviour in development.

RESULTS

Cell cycle dynamics and pluripotency factor expression

To image fluctuations in pluripotency factor gene expression along cell lineages, we used TNGA cells (Chambers et al., 2007), which have GFP inserted directly after the Nanog translational start codon. We chose a stable GFP reporter, which is ideal for observation of long-term fluctuations of gene expression within complete cell cycles and along cell lineages, appropriate for a gene expressed over 2 days and multiple cell cycles in the early mouse embryo (Chambers et al., 2003). A destabilised GFP or direct transcriptional reporter would provide reduced signal-to-noise ratios and require potentially damaging illumination, features unsuitable for quantitative long-term imaging. To facilitate cell tracking, we expressed H2B-mRFP to label nuclei (Fig. 1A). Nuclei were tracked to generate large data arrays of coordinates for mother, daughter and granddaughter cells. Coordinates were used to extract the GFP intensity per unit volume at each time point. An example lineage is shown in Fig. 1A, with the
mother cell indicated by a white arrow, its daughters with yellow arrows and granddaughters with blue. We used large data sets, typically 400-800+ cell lineages per generation per condition. We captured three independent experiments, each with five to seven imaging fields of view for two complete generations. We then captured three further independent pairwise experiments, each with six or seven fields of view, comparing daughter lineages in LIF with daughters in LIF/2i.

To determine the relationship between cell cycle dynamics and pluripotency, we first characterised the basic properties of timing and heterogeneity of ESC cell cycles in LIF. Cycle time was highly heterogeneous within cell populations (Fig. 1B). Median cycle durations were 11-13 h for daughters and 12-14 h for granddaughters (Fig. 1B). The first cycle for cells after addition of 2i-containing media had a longer duration than the corresponding controls (Fig. 1C; Kolmogorov–Smirnov test, \( P<0.0016 \); see supplementary material Appendix S1 for statistics). Increased cycle time was also observed after up to five passages in 2i, relative to controls of similar age (supplementary material Fig. S1D; \( P<5.8\times10^{-5} \)), indicating a sustained reduction of doubling rate.

Variability in cell cycle durations can be used to infer general principles of cell cycle regulation (Brooks, 1981), with several mammalian tissue culture lines showing exponential distributions for differences in division time between sister cells, indicating a control step in the cycle crossed at random (the transition probability model). To test if the transition probability model applies to ESCs, we attempted different fits for frequency plots of interdivision time for sister cells, using a single exponential and a more complex function (Murphy et al., 1984) based upon the Eyring-Stover survival theory (Wullstein et al., 1980) with an environmentally sensitive parameter \( \tau \) in the exponential term (Fig. 1D,E; supplementary material Appendix S1). We carried out a chi-squared goodness-of-fit test, which is independent of heavily weighted bins, for Eyring-Stover and exponential models. The test rejected the exponential in most experiments. By contrast, the Eyring-Stover fit was retained in the majority of cases (supplementary material Appendix S1). For non-related cells, neither model fits the data. Together, these results indicate that the transition probability model is a poor descriptor of the ESC cycle and, unlike other mammalian cell lines, there is likely to be more than one critical step controlling transition through the cell cycle. The more reliable Eyring-Stover fit implies a model with environmental regulation of a rate-limiting step. Environmental influences include growth factor signalling, which can be perturbed in mouse ESCs using 2i. Variability in cycle time (characterised by the coefficient of variation, CV) was slightly increased after multiple passages in 2i (2i/LIF, CV=0.29; LIF, CV=0.23). Difficulties in tracking late-passage 2i-treated cells precluded acquisition of data sets of suitable scale for curve fitting. Instead, we considered cells during their first cycle after 2i treatment. These displayed a slightly extended interdivision time (0.43 h; Fig. 1E). However, this extended interdivision time between sisters is smaller than the overall mean change in cycle times between LIF and 2i/LIF culture (2.2 h), implying that multiple cell cycle transitions are sensitive to 2i.

Cell cycle slowing is coupled to differentiation in many systems (Budirahardja and Gonczy, 2009), so it was surprising that 2i, which reverses differentiation, extended cycles. Studies of cancer stem cell models identified a slow-cycling stem cell state (Sharma et al., 2010). Is pluripotency also a slow-cycling state? To test this in unperturbed cells, we compared cycle time and median Nanog reporter expression (within a cell cycle) for both daughter (Fig. 2A-C) and granddaughter (supplementary material Fig. S1E), in standard serum/LIF culture. Relationships between variables are

Fig. 2. Pluripotency factor expression and cell cycle dynamics. (A) Median expression of Nanog reporter plotted against cycle duration (three replicates). Daughters in LIF are shown with blue circles (n=754), LIF/2i daughters in red (n=822). Cell lineages in both conditions show correlations between cell cycle duration and gene expression. (B) Nanog rate of change versus cycle duration for LIF and LIF/2i. (C) Nanog level from the first 5 h of cycles, plotted against cycle duration for daughters in LIF and LIF/2i. (D) Rex1-GFP expression plotted against cycle duration (434 cells, three replicates, \( r=-0.005 \); a.u., arbitrary units.)
described using Pearson correlation coefficients, which measure the direction and strength of linear dependent relationships between different measurements.

Cycle times were correlated with Nanog reporter expression. Although low expression occurred in both short and long cell cycles, highest levels tended to be in longer cycles. The correlation was weak ($r=0.13$) but significant ($P=0.0018$) for daughter cells from three independent experiments. A similar correlation was observed for granddaughters ($r=0.14$, $P=0.0004$; supplementary material Fig. S1E) and between cycle duration and rate of change of Nanog reporter expression ($r=0.14$, Fig. 2B; supplementary material Table S1). Correlations were not cycle phase dependent, as Nanog reporter levels from the first 5 h of cycles gave similar correlation values to complete cycles (Fig. 2C), implying Nanog reporter expression is not correlated with cycle time specifically because longer cycles have more time to accumulate GFP. Correlations between reporter expression and cycle duration also occurred following treatment with 2i (supplementary material Table S1). In previous experiments in mESCs, artificial expansion of G1 did not alter Nanog levels (Li et al., 2012) and serum level modulation showed a similar resistance of Nanog and Oct4 (Pou5f1) to loss of growth potential (Li and Kirschner, 2014). Together, these data suggest that the extended cell cycle effects we observed are a feature rather than a driver of enhanced pluripotency.

Interactions between expression and cell cycle do not occur for all pluripotency regulators. The Rex1 transcription factor is also heterogeneously expressed in mESCs. We tested whether a reporter cell line (OGR9) with GFP inserted into the Rex1 coding sequence (Toyooka et al., 2008) would reveal connections between expression and cycle time. The observed correlation value was $-0.005$ (Fig. 2D; $n=434$, three repeats). Coherence of Nanog and Rex1 expression has been observed (Toyooka et al., 2008; Singer et al., 2014), although coherence was only partial, so our observations of differences between Rex1 and Nanog in cell cycle coupling might reflect gene-specific differences.

A recent report using TNGA cells suggested disparities between GFP and endogenous Nanog expression (Faddah et al., 2013), with poor correspondence for the GFP-negative population, although the GFP-positive population represented Nanog protein very well. We observed a moderate overall correlation between GFP and Nanog protein levels ($r=0.40$, $n=349$ cells; supplementary material Fig. S1F); however, in agreement with Faddah et al., the GFP population was poorly correlated with Nanog protein levels. Independently considering the GFP$^+$ population elevated the correlation with Nanog protein levels ($r=0.56$, $P=1 \times 10^{-19}$, $n=226$ cells). Given the measurement noise inherent in comparing two different fluorescent channels, this correlation reflects a lower bound estimate. These data, together with the Faddah et al. study, indicate that the GFP$^+$ population is a good measure of Nanog protein levels. To test the effect of the GFP population on our live imaging data, we repeated the analysis with GFP cells screened from the data. The correlations between expression and cycle time were 0.18 ($P=0.0001$) for whole cycles and 0.19 ($P=5 \times 10^{-5}$) for the first 5 h of cycles. After 2i addition, correlations were 0.22 ($P=3 \times 10^{-7}$) for full cycles and 0.13 ($P=0.0004$) for the first 5 h. The unchanged correlation values imply that the interactions between GFP and cell cycle in the TNGA cells are not a consequence of the GFP$^+$ population.

**Cell state restricts Nanog expression dynamics**

It is not clear how Nanog heterogeneity relates to cell lineage and cell cycle stage and how expression dynamics relate to current expression state. To address these issues, we mapped expression and cycle times onto cell lineage data (Fig. 3A) to identify sources of stability and change.

The intergenerational relationships between cells in lineages are displayed as correlation heatmaps in Fig. 3B,C (see also supplementary material Fig. S2). Correlations between different members of lineages for cell cycle duration are shown in Fig. 3B (highest correlations in red, lowest in blue). More closely related cells had more similar cycle times, with daughter pairs and granddaughters both showing strong correlations ($r=0.69 \pm 0.07$ and $r=0.66 \pm 0.12$, respectively) and dilution of this similarity down lineages. Restricting analysis to the GFP$^+$ daughters gave a similar correlation ($r=0.74 \pm 0.04$). Environmental regulation is not clearly apparent here, as granddaughters show lower correlations than daughter sisters, although existing at roughly the same time and place. Strongly correlated daughter cycle times were also observed for OCRG9 cells ($r=0.69 \pm 0.05$). Fig. 3C shows a similar analysis for the Nanog reporter. All cells within a lineage are very strongly correlated, indicating reporter expression fluctuates very slowly. As with cell cycles, closely related members of a lineage were more correlated than more distantly related cells; however, fluctuations within a lineage over two complete cycles were small, with mother-daughter pairs having high correlation values ($r=0.77 \pm 0.03$) and daughter and grandparent pairs showing yet higher correlations in reporter expression ($r=0.91 \pm 0.01$ and $r=0.86 \pm 0.05$, respectively). Restricting analysis to GFP$^+$ daughters also shows a very high correlation ($r=0.83 \pm 0.03$). Some cells fluctuated more rapidly, in agreement with earlier observations (Kalmar et al., 2009; Abranches et al., 2014), although this behaviour was rare. With a mother-daughter correlation of 0.77, lineage correlations would become undetectable after six or seven cell cycles (3 days). Repopulation of full Nanog heterogeneity by purified high reporter cells was previously shown to be complete within 6 days (Chambers et al., 2007), suggesting that fluctuation dynamics are not enhanced in fractionated populations. Strongly correlated expression in sisters was also observed for Rex1-GFP ($r=0.76 \pm 0.09$). The timescales indicated by these high correlations between related cells are longer than the range of fluctuation times of ~2 cell cycles reported for cultured human cells (Sigal et al., 2006) and *Dictyostelium* (Muramoto et al., 2010) and are in line with recent work using different Nanog reporters in culture (Singer et al., 2014) and early mouse embryos (Xenopoulos et al., 2015).

To gain insight into the origins of the strong correlations in cell behaviour within cell lineages, we considered a simple model, using the observed correlation values between mothers and daughters. The model generates two daughters from one mother using linear combination of mother data and a Gaussian random variable along with the intergenerational correlation values known experimentally for Nanog ($r^N=0.77$) and cycle time ($r^C=0.6$) separately. Sampling pairs of values generated a correlation for Nanog between simulated sister pairs of 0.59 (supplementary material Appendix S1) and a cycle correlation of 0.36. Experimentally, these correlations are higher, with $r^N=0.91$ and $r^C=0.69$ for daughter-daughter pairs. These differences between model and data are consistent with a role of the cell environment in stabilising gene expression between generations. Alternative models are: (1) a latent property of the mother, such as reporter RNA, is inherited to both daughters where it is revealed as an enhanced correlation; or (2) mother expression at the point of division may deviate from the median, but will be closer to that of the daughters. Correlations in Nanog and cycle behaviour between sisters were not significantly affected by 2i treatment. In side-by-side experiments, $r^N=0.84$ for both 2i/LIF and LIF alone,
and $r_C=0.75$ versus 0.68, respectively. These data indicate that the processes repressed by 2i, involving MAP kinase and GSK3 signalling, are not required for intergenerational stability.

Sister cells are highly correlated in expression of the Nanog reporter, but correlations fade along cell lineages. At what time in the cell cycle do these differences appear? Fluctuations of reporter expression were measured within individual cycles (Fig. 3D). The difference in expression between sisters was small and relatively stable in the first half of cycles but increased more steeply in the second half. These data suggest the first half of the cycle is dominated by maternally expressed protein and RNA, which when diluted out reveals the dynamic behaviour of each daughter. The analysis in Fig. 3D is insensitive to fluctuations of both sisters in a correlated manner. To investigate the extent to which sister fluctuations are correlated we used a bivariate mean squared displacement (MSD) analysis on Nanog intensity values, decomposing sister time series into summation ($D_1+D_2$) and difference ($D_1-D_2$) components. In the case of independent fluctuations, the summation and difference MSDs are equal. Differences between summation and difference MSDs reflect the degree to which sister intensity fluctuations are linked. Fig. 3E shows that the summation and difference components are not equal, with the difference component showing a significantly lower trajectory, indicating sister cell fluctuations are not independent. The slight curvature of the MSD plots suggests confinement, perhaps indicating a restriction on divergence between cells.

How is the directionality of expression fluctuations altered by transition to the pluripotent ground state? Do all cells induce pluripotency gene expression in 2i? Alternatively, is the transition dominated by selection, with either death or slower cell cycling of low expressers? To distinguish between these possibilities, we measured the change in reporter levels in raw difference plots.
Together, these data suggest no strong environmental determinants. Correlations between intercellular distance and movement were also absent in cells treated with 2i. The simple model described above suggested Nanog and cell cycle regulation by environmental factors. To investigate any local signalling effects, we compared the difference in behaviour between cells as a function of distance for related (red) and unrelated (blue) daughter cell pairs at the beginning (A) and end (B) of cell cycles (see also supplementary material Table S2).

**Regulation of heterogeneity by local environment**

The simple model described above suggested Nanog and cell cycle regulation by environmental factors. To investigate any local signalling effects, we compared the difference in behaviour between cells as a function of distance for related (red) and unrelated (blue) daughter cell pairs at the beginning (A) and end (B) of cell cycles (see also supplementary material Fig. S3A,B). There was no relationship between intercellular distance and GFP (r=0.006). The same comparison is shown in Fig. 4C,D for cycle durations, revealing no evidence for intracellular distance as a determinant of the difference in cycle duration (r=−0.023). These data also indicate that daughters that move apart quickly are no more or less similar than those remaining in close proximity. Correlations between intercellular distance and reporter levels/cycle time were also absent in cells treated with 2i. Together, these data suggest no strong environmental determinants differentiating gene expression and cycle behaviour over the length scale of a field of view (193.5 μm²).

To investigate the possibility of environmental effects over greater length scales, we compared cell behaviours between individual imaging fields of view. We compared the field of view (FOV) average cycle time against FOV average GFP intensity (Fig. 4E). The correlation between cycle time and expression was higher in FOV average data (r=0.60) than single-cell data (r=0.13, see above) for daughters (three independent experiments). For the corresponding granddaughters, the correlation value was 0.63. The repeat test (daughters only, three independent experiments) gave r=0.37. After bootstrapping the data by randomising values between fields (see supplementary material Appendix S1), the probability that the correlation value of 0.6 between Nanog/cycle duration would occur randomly was 0.018 and 0.12 for r=0.37. So the increased correlation observed between field-averaged cell cycle and Nanog reporter expression may constitute a weak effect. A recent study (Kumar et al., 2014) found that individual ESC colonies had homogeneous expression of pluripotency markers, including Nanog, which the authors interpreted as inheritance of expression states over multiple generations. The differences in magnitude of the effects in our data and the Kumar et al. study might be due to culture conditions. In our serum/LIF culture, most cells grow as a rough monolayer, although compact vertically projecting colonies are occasionally observed. A mathematical model for culture progression from single founder cells, constrained by the inheritance values measured in our study (Fig. 4F), suggests high local correlations in cell behaviour would not arise from inheritance. Although the model used high mother-daughter correlation values (r=0.77 for Nanog), the simulated FOV cell cycle-Nanog correlation at our culture densities declined to the level of the single-cell correlation by the time the simulated culture was at the cell density used experimentally (Fig. 4G). We infer that any strong local correlations in cell behaviour would be derived, in part, from local signalling, rather than purely inherited behaviour. We commenced imaging when there were 10-30 cells in a FOV. Based on the cell cycle times we measured in this study, it is unlikely that one founder cell in a FOV could generate 10-30 cells between the time of plating and the time of imaging (18 h), so our model might overestimate the inheritance component.

Cell movements are an integral part of early mouse development (Plü Walter et al., 2008), sorting cells out and introducing them to novel stimuli (Xenopoulos et al., 2012), implying that cell motility might regulate the heterogeneous behaviours of ESCs. We investigated motility of TNGA cells using MSD analysis of distance moved. MSD plots of TNGA cells indicate a more complex model of translocation than random walk diffusion alone. Fig. 5A shows MSD as a function of lag between time points. The fit is non-linear and slightly upwardly curving, indicating random walk with flow, perhaps resulting from cells moving into available space, with resistance to motility from increasing cell density at source. Similar trajectories were observed with LIF and LIF/2i. Although the plot suggests enhanced motility of cells in LIF compared with cells entering 2i, suggesting an effect of enhanced local pockets of cell density in 2i, no strong change in diffusion coefficient was observed with data pooled from three independent experiments (1.13 μm²/min for LIF and 0.98 μm²/min for LIF/2i). A slight flattening of the trajectory was observed in some MSD plots, perhaps an effect of the limited size of a FOV. Motility showed weak but significant negative correlations with both cell cycle and Nanog reporter (supplementary material Table S2).

An alternative metric to describe local environment is cell density. Density was calculated by measuring the level of nuclear red fluorescence within 50 pixel diameter circles centred on cell centroids. We measured correlations for each cell between density and reporter expression at each time point (supplementary material Fig. S3C,D). Peak correlation values were slightly positive, but the spread was high and apparent weak correlations non-significant. However, if we use the median cell density from whole cycles, this showed significant positive correlations with both cell cycle duration and Nanog reporter expression (Fig. 5B; supplementary material Table S2) for daughters (r²=0.25, r=0.34) and granddaughters (r²=0.18, r=0.28). Anti-correlations between density and motility were observed in both LIF and 2i/LIF and are likely to reflect obstructions to cell migration. Correlation between Nanog reporter and density was clear in GFP⁺ cells (r=0.26,

\[ P = 1 \times 10^{-8} \]

and persisted into 2i, although the link between cell cycle and density was lost in 2i. Similar to Nanog reporter cells, density was correlated both with cycle duration \((r=0.12, P=0.01)\) and Rex1 reporter expression in OCRG9 cells \((r=0.22, P=6 \times 10^{-6}; \text{Fig. 5C})\). The implied role of density in the regulation of ESC behaviour may parallel the anecdotal image of the ESC colony with a dense 3D mass of pluripotent cells surrounded by the flatter and more polarised differentiating cells. Although in our serum/LIF cultures the structures that the cells form are generally monolayer-like, considerable heterogeneity in cell aggregate morphology within a culture does exist.

**DISCUSSION**

We have developed a high-content imaging and analysis platform for parallel measurement of multiple dynamic cellular and population features of mouse ESCs, together with gene expression, using large data sets. Our analysis revealed that mESC cell cycles are highly variable in duration. Analysis of this variability indicated that cycles are regulated at multiple transition points, unlike other standard cell lines. High Nanog reporter expression is associated with longer cell cycles, and 2i, which drives pluripotency, increased both cycle duration and variability. Fluctuations in cycle duration and gene expression were slow, with closely related cells retaining very similar cycle times and expression. The expression state of the cell is a strong indicator of its future state, although high expressers tend to reduce their expression and low expressers increase their expression. The cell environment also interacts with Nanog expression and cycle behaviour. Local intercellular signalling interactions are not strong over short timescales; however, cell density emerges as a recurrent feature,

Fig. 4. Regulation of ESC heterogeneity by local environment. (A-D) Comparison of intercellular distance and differences in Nanog expression (A,B) and cell cycle duration (C,D) for a representative experiment. Distances between related (red) and unrelated (blue) daughters at birth (A,C) and subsequent mitosis (B,D). See supplementary material Fig. S3A,B for replicates. (E) Field of view (FOV) average cycle time plotted against field-average GFP intensity (three experiments; 18 FOVs; \( r=0.6 \)). Each experiment is shown in a different colour. Data from repeats normalised to the same mean and s.d. Correlations between cycle time and expression were higher in FOV than in single cells. (F) A simple model in which daughter cells inherit Nanog and cycle behaviour directly from mothers using experimentally determined correlation values, simulating the changing correlations between cell cycle and Nanog based upon the lineage of one founder cell \((r, \text{correlation}; m, \text{mother}; d, \text{daughter}; N, \text{Nanog level}; c, \text{cycle duration})\). (G) Multigenerational simulation of the model, assuming all cells in a FOV derived from one founder. Values on the vertical axis are FOV correlations between cycle duration and GFP (curves for different hypothetical starting correlations shown). For experimental data, imaging began at \( \sim 10-30 \) cells for two cell cycles, corresponding to generations 5-6 in the figure. Correlations at generation 5-6 were higher in experimental data than in simulations, regardless of the starting correlation level, consistent with local environment stabilising cell behaviour.
for both cycle behaviour and pluripotency factor gene expression. The link between density and cycles might be a contact inhibition phenomenon. For density and gene expression, there may be similarity with the early embryo, with Nanog becoming restricted to the inner cell mass, then epiblast (Chambers et al., 2003), which will perceive a greater number of cell-cell contacts than prospective extra-embryonic tissue. Parameterised models underpin the importance of cell-cell coupling in the long-term stability of gene expression states. Analysis of expression of the Rex1 pluripotency factor indicated partially overlapping features with Nanog regulation.

Comparing our results with previous studies of Nanog dynamics identifies apparent differences, which can be explained by the enhanced scale of our data set and the different approaches used. In an early study using TNGA cells (Kalmar et al., 2009), Nanog showed fast switching between states. Although we observed some large fluctuations over timescales of cell cycles, these were infrequent. In this early study cells were flow-sorted before imaging, providing a different population context. A recent study using a destabilised reporter also observed fast fluctuations (Abranches et al., 2014). Stable GFP reporters reveal a time-integrated view of transcription, showing the combined behaviour of several bursts of a destabilised reporter. A recent study imaging endogenous pluripotency factor levels using antibodies and single-molecule RNA fluorescent in situ hybridisation (Kumar et al., 2014) suggests very low heterogeneity in closely related cells and implies long-term stable transcriptional behaviour, which parallels the stability of Nanog reporter expression in pre-implantation mouse embryos (Xenopoulos et al., 2015) and a recent in vitro study (Singer et al., 2014). Recent work also showed no obvious differences in fluctuation range or rate between LIF and LIF/2i (Abranches et al., 2014; Singer et al., 2014). Our study shows an increase in fluctuation range in 2i, which is likely to be because we measured the transition to 2i, not the 2i steady state. If the fluctuation range did not alter after 2i treatment, other mechanisms, such as selection, would be required to generate a uniform high Nanog state. We saw no such evidence of selection, with slower cell cycles and no increase in cell death after 2i treatment. The Abranches et al. study observed no bias in mitotic division time related to Nanog reporter level. Our data are consistent with this, although we observed a clear anti-correlation between reporter levels at the beginning of the cell cycle and at the end, an observation made clearer by the scale of our data set and the clarity of a stable reporter generating a time-integrated signal.

ESC cell cycle control appears more complex than in other mammalian cell culture models. Initial studies on interdivision times between sister cells revealed a single rate-limiting transition (Brooks, 1981) for several mammalian cell lines. Subsequent work showed the variability between unrelated cells in a population could be explained by two rate-limiting steps (Brooks et al., 1980) or a more complex environmentally regulated step (Murphy et al., 1984). Our data indicate that a single rate-limiting step (the transition probability model) is not sufficient to explain interdivision times of ESC sisters, and that a more complex environmentally regulated model does not fit data from non-related cells in the population. In addition, the increase in interdivision times between sister cells in 2i is small compared with the overall increase in cycle time observed in 2i. Together, these data are consistent with a model in which ESC cycle progression is actively regulated at multiple phases.

Average cycle durations were increased in high Nanog reporter cells, although high variability in cycle duration was observed in all conditions. Cycle times were further increased after 2i, although longer cell cycles were still associated with cells with higher reporter expression. Differentiation is usually associated with slowing of the cycle, so observing slower cycles for a less differentiated state was initially surprising. Slow-cycling stem cell states were previously inferred in cancer biology, although differences in cycle times (Sharma et al., 2010) are more extreme. Previous studies did not observe changes in Nanog expression caused by disruption of growth potential or G1 (Li et al., 2012; Li and Kirschner, 2014). Together, these data indicate that longer cell
cycles are a feature, rather than a cause, of the pluripotent state. Frequent use of system-wide regulators such as cell cycle kinases and associated networks might not be compatible with cells remaining in the metastable attractor state proposed for stem cells (Huang, 2011). Consistent with the attractor view, cells expressing high levels of the reporter tend to decrease reporter expression. One might view this as an epigenetic barrier, such as the side of one of Waddington’s valleys (Waddington, 1957) or the wall of an attractor (Huang, 2011) driving reversion to a local mean. The persistence of a significant proportion of the cell population showing overall down transitions following 2i treatment suggests a probabilistic search through the new attractor landscape, not switch-like behaviour. An alternative explanation is that the different behaviours after the different treatments reflect pre-existing heterogeneities in state, inferred as a source of differential induced pluripotent stem cell (iPSC) reprogramming potential (Pour et al., 2015).

We have identified a variety of cellular and population-level features coupled with Nanog fluctuations. However, most features are highly heterogeneous — our data indicate tendencies, not determinism, which raises the conjecture that ‘stemness’ is unlikely to be explained, or derived, by a ‘magic bullet’. It will be interesting to see how these conclusions are borne out in other developmental contexts. Our approaches concern the central problem in developmental biology of how cells become different, and these contexts ultimately provide the basis for large-scale dynamic imaging methods are therefore expected to be generically applicable to developmental biology of how cells become different, and these contexts.

Two-sample Kolomogorov-Smirnov test

A two-sample Kolmogorov-Smirnov test was used to compare the daughter and granddaughter distributions of median Nanog intensity, with the null hypothesis that the daughter and granddaughters are sampled from the same underlying distribution.

The test is based on the maximal absolute difference in the two cumulative distribution functions:

$$\max (|F_1(x) - F_2(x)|)$$

We used a standard 5% significance level to reject null hypotheses. However, as we compared three experiments and are essentially performing three comparisons, we adjusted the p-value using a correction for multiple comparisons to prevent an increase in false positives. The Bonferroni correction method divides the significance level, $\alpha$, by the number of tests, while the Šidák correction uses the family-wide error rate, $\alpha = 1 - (1 - \alpha)^{1/n}$. The table below summarizes the outcome of the K-S tests using the two correction methods, showing that no significant differences are observed between the Nanog intensity distributions of daughters and granddaughters.

Section B

Fitting cell cycle data

Two fits were tested on plots for the fraction of undivided sister cells remaining in Figures 1D and E. The first fit is a simple exponential of the form:

\[ B = e^{-\alpha \Delta}, \]  \hspace{1cm} (1)

where \( \alpha \) is the fitting parameter with units of (hours \(^{-1}\)) and \( \Delta t \) is the time difference in hours. The second fit, based upon the Eyring-Stover (ES) survival theory (Murphy et al., 1984) has the form:

\[ B = 2(1 - e^{\alpha \Delta t})^{-2}[1 + (\alpha \Delta t - 1)e^{\alpha \Delta t}] \]  \hspace{1cm} (2)

For our LIF data, the exponential fit is rejected in the majority of cases (see the table below). The more reproducible fit of equation 2, implies that more than one control step may be involved in the cell cycle transitions. The goodness of fit was tested using a chi-squared test as discussed in the main text. For the non-related cells in LIF, neither equation fits.

Section C
MSD analysis
By analogy with the random walk of diffusing particles, we investigated the fluctuations in Nanog intensity using an MSD (mean squared displacement) analysis. In terms of Nanog intensity, the mean squared deviation is defined as:

\[ MSD(\tau) = \langle (I(t + \tau) - I(t))^2 \rangle \tag{3} \]

Where \( I \) is the Nanog intensity, \( t \) is the time and \( \tau \) is the lag time. The form of the MSD provides information of the magnitude and timescale of fluctuations – a linear MSD describes purely random walk behaviour, while a plateau is suggestive of the value being constrained or corralled.

The data in Figure 3D show the difference between sister intensities remained small for a time after division, suggested that sister intensities may fluctuate in a correlated manner. To investigate this further, we decomposed the two sister intensities into an alternative orthogonal basis set, rotated by 45 degrees from the standard representation:

\[
I_s = \frac{1}{\sqrt{2}} (I_1 + I_2) \\
I_d = \frac{1}{\sqrt{2}} (I_1 - I_2) \tag{4}
\]

In this notation \( I_s \) can be thought of as the summed intensity, measuring fluctuations which are common to both sisters while \( I_d \), the difference intensity, quantifies fluctuations where one sister moves in the opposite direction to the other. Using the theory of the combination of random variables, if fluctuations in \( I_1 \) and \( I_2 \) are completely independent then MSD(\( I_s \)) and MSD(\( I_d \)) are expected to be equal, while if the behaviour is correlated then MSD(\( I_d \))>MSD(\( I_s \)). The contrasting case of anti-correlated fluctuations would yield MSD(\( I_d \))>MSD(\( I_s \)).

MSD for motility
By analogy with the random walk of diffusing particles, we investigated the cell movement using an MSD (mean squared displacement) analysis. The mean squared deviation is defined as:

\[ MSD(\tau) = \langle (I(t + \tau) - I(t))^2 \rangle \tag{4} \]
Where I is the cell co-ordinates, \( t \) is the time and \( \tau \) is the lag time. The form of the MSD provides information of the magnitude and timescale of fluctuations – a linear MSD describes purely random walk behaviour, while a plateau is suggestive of the value being constrained or corralled. Here we find that an active transport fit best describes the movement of cells in both LIF or LIF + 2I conditions.

\[
< r^2 > = 4D\Delta t + v^2 \Delta t^2
\]

Where \( D \) is the Diffusion constant in \( \mu m^2/\text{min} \) and \( v \) is the drift term (velocity of drift) in \( \mu m/\text{min} \):

**Section D**

**Bootstrapping field-of-view correlations**

Cell cycle lengths and Nanog pairs were randomised between field-of-views to test the possibility that the field-of-view correlations between Nanog and cell cycle length were simply enhanced from the individual cell cycle and Nanog correlations. The mean correlation once randomised was 0.11 + 0.19 (Figure S3B), which is within the range of the individual correlation between Nanog and cell cycle lengths of 0.13, for daughters. This can be shown mathematically:

Let \( F = \text{field-of-view average of } X \) (cell cycle lengths) and \( G = \text{field-of-view average of } Y \) (Nanog)

The mean of \( F \) and \( X \) are equal (\( \mu_F = \mu_X \)) as are the mean of \( G \) and \( Y \) (\( \mu_G = \mu_Y \)), and the standard deviations of \( F \) and \( G \) are:

\[
\sigma_F = \frac{\sigma_X}{\sqrt{N}} \quad \sigma_G = \frac{\sigma_Y}{\sqrt{N}}
\]

The covariance of \( F,G \) is:

\[
COV(F, G) = E((F - \bar{F})(G - \bar{G})) \quad (5)
\]

\[
COV(F, G) = E \left[ \left( \frac{\sum_{i=1}^{N} X_i}{N} - \frac{\mu_X}{N} \right) \left( \frac{\sum_{i=1}^{N} Y_i}{N} - \frac{\mu_Y}{N} \right) \right]
\]
Therefore, once randomized, the correlation between field average Nanog and cell cycle lengths should be equal to the individual correlation between Nanog and cell cycle length, as we have observed.

### Section E

#### Modelling inheritance of Nanog expression

The simplest model generates two daughters from one mother using the correlation values known experimentally from mother to daughter for Nanog \((r = 0.77)\) and cell cycle length \((r = 0.6)\) separately.

In the derivations which follow, it is assumed that any variables have been normalized such that their distributions have zero mean and unity standard deviation. This simplifies the calculation of the product moment correlation coefficient. If required, the final variables can be converted back to their unnormalized values, however parameters such as the correlation coefficient are invariant to shifting and scaling.

Data sets for daughters can be produced by a linear combination of the mother data and a Gaussian random variable; the relative weight of the mother contribution determines the strength of the correlation. If:

\[
d_i = \alpha M + \beta Z,
\]
Where \( Z = N(0,1) \), the constraint \( \alpha^2 + \beta^2 = 1 \) ensures that the resulting distribution has a standard deviation of unity. The correlation coefficient between mother and daughter is then given by:

\[
\begin{align*}
    r_{md} &= \text{cov}(M, \alpha M + \sqrt{1-\alpha^2} Z) \\
    r_{md} &= \alpha \text{cov}(M, M) + \sqrt{1-\alpha^2} \text{cov}(M, Z) \\
    r_{md} &= \alpha
\end{align*}
\]

Therefore daughter data is generated from the mother values as follows:

\[
\begin{align*}
    d1 &= r_{cmd} M + \sqrt{1 - r_{cmd}^2} Z_{d1} \quad (6) \\
    d2 &= r_{cmd} M + \sqrt{1 - r_{cmd}^2} Z_{d2}
\end{align*}
\]

Where \( M \) is the mother cell cycle lengths, \( r_{cmd} \) is the correlation between mother to daughter cell cycle lengths experimentally calculated and \( Z_{d1} \) and \( Z_{d2} \) are random variables generated. The correlation between sisters can be calculated from:

\[
    r_{cdd} = \frac{\text{cov}(d1,d2)}{\sigma_{d1}\sigma_{d2}} \quad (7)
\]

The only non-zero term in the above equation is \( \text{cov}(M,M) = 1 \), leaving

\[
    r_{cdd} = r_{cmd}^2
\]

Performing 100 repetitions of the model and using 16 experimental mother cells (a typical starting number of mother cells) produces an average correlation between the new daughter Nanog sister pairs of 0.59 ± 0.05 and an average correlation between cell cycle sister pairs of 0.36 ± 0.09. However, experimentally these correlations are 0.91 ± 0.01 and 0.69 ± 0.007. One possibility is that stability of Nanog reporter levels and cell cycle lengths between mothers to daughters may be enhanced by environmental regulation to generate unexpectedly high correlations between daughters. Alternatively, this may arise, if the state of the mother cell changes between the point at which the median density applies and the time of division, and this changed state is then transmitted to the daughter cells.

**Section F**

**Constraining the model: sister pairs**

In order to replicate the field-of-view correlations experimentally observed, the model must also contain the correlations between sister pairs for both Nanog and cell cycle length.
Therefore, as described above, we add an intermediate state after the mother state, from which daughter data is independently generated:

If $r_{MI}$ is the correlation between mother and intermediate state, and $r_{Id}$ is the correlation between intermediate state and daughter 1 or 2, following the same process of covariance calculation as in section D yields:

$$r_{dd} = r_{Id}^2$$

$$r_{Md} = r_{MI} r_{Id}$$

These results can be rearranged to give the values of $r_{MI}$ and $r_{Id}$ required for the desired mother-daughter and daughter-daughter correlations:

$$r_{MI} = \frac{r_{Md}}{\sqrt{r_{dd}}} \quad (8)$$

$$r_{Id} = \sqrt{r_{dd}}$$

Using this framework, data for the current generation can be produced from the previous generation values, matching the values of mother-daughter and daughter-daughter correlations to those observed experimentally, to test if the observed Nanog-cell cycle correlation could arise from the relatedness of cells in the field-of-view. Starting with one mother cell (this is the most extreme case, all cells would arise from one original cell), 10 generations are produced for each of the seven fields-of-view (replicating experiment 3), with cell numbers doubling each time (1, 2, 4, 8, 16 etc); this whole process is repeated 1000 times. An average Nanog and Cell cycle length is calculated for every field. From this an average correlation value is produced for each generation. The correlation value of average Nanog reporter and cell cycle of fields-of-view decreased rapidly to 0. So even in the extreme case of starting with one mother cell the strong correlation between mother to daughter for Nanog and cell cycle length is not solely sufficient to produce such a strong correlation (0.60) at the field-of-view level.

**Section G**

**Constraining the model: Cell Cycle and Nanog**

Experimentally, there is a low correlation between Nanog levels and cell cycle length which is not included in model B.
As in section E, where sisters are more correlated than independent generation from the mother values would give, an intermediate state is created from which the two daughters are generated. However, since we wish to maintain a correlation between cell cycle length and Nanog intensity, these variables are generated simultaneously from a correlated bivariate distribution.

\[ I_c = r_{cm}m_c + \sqrt{1 - r_{cm}^2} Z_c \]
\[ I_N = r_{Nm}m_N + \sqrt{1 - r_{Nm}^2} Z_N \]
\[ d_c = r_{cd}I_c + \sqrt{1 - r_{cd}^2} W_c \]
\[ d_N = r_{Nd}I_N + \sqrt{1 - r_{Nd}^2} W_N \]

Where \( Z_c \) and \( Z_N \), and \( W_c \) and \( W_N \) are correlated random variables with correlation coefficient \( r_Z \) and \( r_W \) respectively. The values of \( r_Z \) and \( r_W \) (that is, the value of the correlation for the random mixing variables) are calculated so as to maintain the value of the correlation coefficient between cell cycle length and Nanog from one generation to the next:

\[ r_{cN} = r(I_c, I_N) \]
\[ r_{cN} = r(r_{cm}m_c + \sqrt{1 - r_{cm}^2} Z_c, r_{Nm}m_N + \sqrt{1 - r_{Nm}^2} Z_N) \]
\[ r_{cN} = r_{cm}r_{Nm}r(m_c, m_N) + \sqrt{1 - r_{cm}^2} \sqrt{1 - r_{Nm}^2} r(Z_c, Z_N) \]
\[ r_{cN} = r_{cm}r_{Nm}r_{cN} + \sqrt{1 - r_{cm}^2} \sqrt{1 - r_{Nm}^2} r_{cN} \]

\[ r_Z = \frac{r_{cN} - r_{cm}r_{Nm}r_{cN}}{\sqrt{1 - r_{cm}^2} \sqrt{1 - r_{Nm}^2}} \]  \( (9) \)

When adding single cell Nanog reporter-cell cycle correlations in to the model (Figure S3C) we observe that the correlation between fields will plateau at the individual cell cycle length and Nanog correlation for granddaughters of 0.14 (Figure S3D). Again this implies the field-of-view effect is not caused by a small number of related cells at the beginning of image acquisition.

**Section H**

**Alternative Background Correction Method**

Background was estimated for each pixel by accumulating and averaging pixel intensities for frames when no cell was present. The decision whether a cell is present in the pixel was made
by smoothing with a Gaussian kernel and applying a threshold. In densely populated regions, there may be insufficient samples of a pixel to accurately calculate the background intensity; pixels with fewer than 40 samples throughout a movie were filled in using an iterative diffusion algorithm. This yields a map of the estimated background intensity at each xyz location of movies, allowing the position-dependent background intensity to be subtracted from cell intensity measurements.

Heterogeneous Nanog expression and cell cycle behaviour

A) Flow cytometry data showing bimodal distribution of GFP expression driven by the Nanog promoter under LIF culture conditions. B) Distributions of Nanog expression from 3 experiments for daughters and granddaughters. The median value was taken from each cell from its entire cycle. A two-sample Kolmogorov-Smirnov test showed that the distribution of Nanog expression levels was unchanged between daughters and granddaughters. C) Distributions of Nanog expression levels from all 3 experiments in LIF or in LIF after the addition of 2i. D) Cell cycle durations of cells after 5 passages in 2i, compared to similar culture age controls. 2 independent experiments (2i n=167 cells, LIF n=119). E) Median GFP expression from the Nanog gene plotted against cell cycle duration for all complete cell cycles from 3 independent experiments for granddaughter cells (n=632). F) Comparing GFP expression and Nanog protein expression in TNGA cells by immunofluorescence (349 cells total). Cells were fixed in 4% paraformaldehyde, and stained with a rabbit polyclonal to the Nanog protein (Abcam ab80892; 1 in 100) and Cy3 conjugated anti-rabbit secondary. Images were captured on a Perkin Elmer Vox spinning disc microscope. Excluding the low Nanog population gave a correlation between GFP and Nanog antibody staining of 0.56 (226 cells).
Figure S2
Intergenerational correlations in cell cycle and Nanog dynamics
Intergenerational correlation heatmaps from independent experimental repeats for cell cycle durations (A and C) and Nanog (B and D). These panels are the replicates of Figure 3B and C.
