Nf1 limits epicardial derivative expansion by regulating epithelial to mesenchymal transition and proliferation

Seung Tae Baek and Michelle D. Tallquist*

SUMMARY

The epicardium is the primary source of coronary vascular smooth muscle cells (cVSMCs) and fibroblasts that reside in the compact myocardium. To form these epicardial-derived cells (EPDCs), the epicardium undergoes the process of epithelial to mesenchymal transition (EMT). Although several signaling pathways have been identified that disrupt EMT, no pathway has been reported that restricts this developmental process. Here, we identify neurofibromin 1 (Nf1) as a key mediator of epicardial EMT. To determine the function of Nf1 during epicardial EMT and the formation of epicardial derivatives, cardiac fibroblasts and cVSMCs, we generated mice with a tissue-specific deletion of Nf1 in the epicardium. We found that mutant epicardial cells transitioned more readily to mesenchymal cells in vitro and in vivo. The mesothelial epicardium lost epithelial gene expression and became more invasive. Using lineage tracing of EPDCs, we found that the process of EMT occurred earlier in Nf1 mutant hearts, with an increase in epicardial cells entering the compact myocardium. Moreover, loss of Nf1 caused increased EPDC proliferation and resulted in more cardiac fibroblasts and cVSMCs. Finally, we were able to partially reverse the excessive EMT caused by loss of Nf1 by disrupting Pdgfrα expression in the epicardium. Conversely, Nf1 activation was able to inhibit PDGF-induced epicardial EMT. Our results demonstrate a regulatory role for Nf1 during epicardial EMT and provide insights into the susceptibility of patients with disrupted Nf1 signaling to cardiovascular disease.

INTRODUCTION

The epicardium, which comprises the outer epithelial layer of the heart, is a cell population that undergoes epithelial to mesenchymal transition (EMT) during development (Lie-Venema et al., 2007). Around embryonic day (E) 13.5, a subset of epicardial cells lose their epithelial characteristics, gain mesenchymal properties and migrate into the heart to differentiate into coronary vascular smooth muscle cells (cVSMCs) and cardiac fibroblasts (Dettman et al., 1998; Manner et al., 2001; Mikawa and Gourdie, 1996). Several growth factors, including transforming growth factor α (TGFβ) (Mercado-Pimentel and Runyan, 2007; Xu et al., 2009b) and fibroblast growth factor (FGF) (Pennisi and Mikawa, 2009) have been implicated in the EMT process of epicardial cells during heart development, but little is understood about signals that limit the EMT process. Identification of such pathways will provide insights into the complex regulation of EMT during heart development. Because many of these same signaling pathways have also been suggested to play a key role in cardiac fibrosis, this might also provide insights into pathological EMT.

Recent findings show that disruption of Ras/mitogen activated protein kinase (MAPK) signaling results in several syndromes that exhibit congenital heart defects, including the Costello (Aoki et al., 2005), LEOPARD (Kontaridis et al., 2006), cardio-facio-cutaneous (Nihori et al., 2006) and Noonan (Schubbert et al., 2006) syndromes. Loss of neurofibromin 1 (Nf1; also known as neurofibromatosis-related protein NF-1), a Ras-GTPase activating protein (GAP), leads to hyperactivation of Ras and its downstream components (Cichowski and Jacks, 2001; Martin et al., 1990; Xu et al., 1990). Although mutations in Nf1 are best known for causing neurofibromatosis type 1 tumors of the skin and nervous system (Lynch and Gutmann, 2002), patients with Nf1 mutations also have an increased risk for cardiovascular disorders (Lin et al., 2000).

Studies in mice have significantly advanced our understanding of Nf1 function during heart development. Inactivation of Nf1 causes lethality at mid-gestation, with severe heart defects including malformation of the outflow tract, a thinned myocardium, a ventricular septal defect and enlarged endocardial cushions (Brannan et al., 1994; Jacks et al., 1994). Loss of Nf1 in vascular smooth muscle cells (VSMCs) leads to an abnormal proliferative injury response (Xu et al., 2007), and cardiomyocyte-specific inactivation of Nf1 results in pathological hypertrophy and heart failure in adult mice (Xu et al., 2009a). Nf1-null endocardial cushion cells exhibit abnormal EMT (Lakkis and Epstein, 1998), and endothelial-specific deletion of Nf1 recapitulates many of the cardiovascular defects of the Nf1-null mouse, suggesting an indispensable role of Nf1 in endothelial cells during EMT (Gitler et al., 2003).

We have investigated the function of Nf1 in epicardial development using Cre/loxP technology to inactivate Nf1 in the mouse epicardium. We found that loss of Nf1 results in increased EMT and epicardial-derived cell (EPDC) proliferation, leading to a substantial expansion of this cell population that includes cardiac fibroblasts and cVSMCs. Our data point to a regulatory role for Nf1 in the process of EMT and suggest the possibility that patients with disruption of Nf1 might be more prone to cardiac complications such as fibrosis and coronary artery disease.

MATERIALS AND METHODS

Mice

Mice were maintained on a mixed C57/BL6 × 129SV background. Mice with the Gata5-Cre transgene (Merki et al., 2005) or Wt1CreEPFDC allele (Zhou et al., 2008) were crossed with mice with the Nf1 floxed (Nf1fl/fl) allele (Zhu et al., 2001) to generate Nf1fl/fl;Gata5-Cre (designated Nf1G5KO) and...
Dr William Pu (Harvard, MA, USA) and X-LacZ4 Tg
Wt1GFPCre
by Dr Luis Parada (University of Texas Southwestern, TX, USA) and Dr Committee of the University of Texas Southwestern Medical Center and strains in these experiments include administrated at a final concentration of 0.1 mg per gram body weight. Other mice with induced by oral administration of tamoxifen (MP Biomedicals, 02156738) PdgfraGFP al., 1998) or with antibodies against vimentin (1:500; Sigma, V6630), SM-MHC. The SM-MHC-positive area was measured and divided by the DAPI stain as previously described (Mellgren et al., 2008). Epicardial differentiation of mesenchymal cells was confirmed by qRT-PCR. For immunostaining, hearts were cultured in 24-well plates. Loss of Nf1 in Nf1G5KO cultures was confirmed by qRT-PCR. For immunostaining, hearts were placed on glass coverslips coated with collagen type IV (5 μg/cm², R&D Systems). Collagen-coated coverslips were prepared according to the manufacturer’s protocol. For the in vitro differentiation assay, epicardial cells were cultured for a total of 6 days followed by immunostaining. Ex vivo migration assay
The ex vivo migration assay was performed as described (Mellgren et al., 2008). E12.5 hearts were isolated and incubated with adenovirus expressing GFP or Nf1 GAP-related domain (Miller et al., 2010), kindly provided by Dr Robert Gerard or Dr Nancy Ratner (Cincinnati Children’s Hospital, OH, USA), respectively. PDGF-BB (R&D Systems), imatinib mesylate (Sigma), AG1296 (Sigma) and U0126 (Sigma) were added to the cultures as indicated. After 2 days, hearts were fixed in 4% PFA and frozen embedded, sectioned and stained for DAPI. For quantification, GFP+ cells underneath the epicardium were counted in a 40× field of view from five nonconsecutive sections. Quantification and statistical analysis
For mesenchymal index, primary cultured epicardial cells were stained for β-catenin and phalloidin as described above, and cells exhibiting a mesenchymal morphology were identified by the loss of adherens junctions and cortical actin and by the robust formation of actin stress fibers (Sridurongrit et al., 2008). Mesenchymal cells were counted and divided by the total number of cells in a 40× field of view from three different regions of the cultures. β-galactosidase staining was quantified as previously described (Morgan et al., 2008). Epicardial differentiation of smooth muscle cells was quantified following immunostaining against SM-MHC. The SM-MHC-positive area was measured and divided by the DAPI positive area in three 40× field-of-view images using ImageJ (NIH). All experiments used a minimum of two independent litters, and data were analyzed by Student’s t-test using Prism 5 (GraphPad Software).
qRT-PCR
Primary epicardial cells were collected as described above. RNA isolation and cDNA synthesis were as described previously (Mellgren et al., 2008) with slight modifications. Briefly, primary epicardial cultures from three hearts of each genotype were combined followed by RNA isolation using Trizol (Invitrogen). cDNA was synthesized using Superscript III reverse transcriptase (Invitrogen). Gene transcription was analyzed by standard qRT-PCR with iTAQ SYBR Green Master Mix (Bio-Rad) using the CFX36 real-time PCR detection system (Bio-Rad). Each sample was run in triplicate. Sequences of primers are as reported previously (Smith et al., 2011). In situ hybridization on tissue sections
Section in situ hybridization was performed as described previously (Schaeren-Wiemers and Gerfin-Moser, 1993; Smith et al., 2011). Briefly, embryonic hearts were isolated, fixed in 4% PFA, frozen embedded and...
RESULTS

Epicardial inactivation of Nf1 results in aberrant epicardium development

Loss of Nf1 in cardiomyocytes or the endocardial cushions results in heart abnormalities (Gitler et al., 2003; Xu et al., 2009a), but no reports have addressed the disrupted epicardium observed in Nf1-null hearts (Brannan et al., 1994). To determine whether Nf1 has a primary role in epicardial development, we performed in situ hybridization for Nf1 transcripts. Nf1 expression was detected in the epicardium, endocardium, endocardial cushions and myocardium at E11.5, but by E12.5 myocardial expression was decreased (supplementary material Fig. S1). Epicardial expression continued until E13.5, but by E14.5-15.5 was limited to a few cells in the epicardium (Fig. 1A; supplementary material Fig. S1).

To investigate Nf1 function in epicardial development, we initially used two mouse lines with constitutive expression of Cre in the epicardium: the Gata5-Cre<sup>E2</sup> (Merki et al., 2005) and the Wt1GFPCre (Zhou et al., 2008) mouse lines. We monitored loss of Nf1 transcript by Gata5-Cre<sup>E2</sup>-driven recombination (referred to as Nf1<sup>G5KO</sup>) and found little expression in the epicardium and endocardial cushions at E13.5 (Fig. 1B). Using Wt1 protein expression to track the epicardium and undifferentiated EPDCs (Moore et al., 1999) we found that, unlike control hearts in which Wt1<sup>+</sup> cells were restricted to the epicardium at E12.5, Wt1<sup>+</sup> cells in Nf1<sup>G5KO</sup> hearts were detected in not only the epicardium but also the subepicardial zone (Fig. 1C). To determine whether these cells had adopted a mesenchymal phenotype, we stained for vimentin, a marker for mesenchymal cells that often indicates that a cell has undergone the process of EMT (Perez-Pomares et al., 1997). At E12.5, control hearts had few vimentin<sup>+</sup> cells in the subepicardium (Fig. 1D), whereas in Nf1<sup>G5KO</sup> hearts there were multiple patches of vimentin<sup>+</sup> cells in the subepicardium. These patches were often concomitant with a disrupted basement membrane (collagen IV staining; Fig. 1D). Similar patches of vimentin<sup>+</sup> cells were also found when Nf1 expression was disrupted using a Wt1CreGFP<sup>E2</sup> allele for recombination (Fig. 1D).

Based on ROSA26 reporter activity, both of these epicardial Cre lines recombine in a significant number of cardiomyocytes and in the endocardial cushions (data not shown). Therefore, we performed the remaining in vivo experiments employing the

inducible epicardial-specific Cre mouse Wt1CreERT2 (Zhou et al., 2008). First, we confirmed the fidelity of recombination in this line to demonstrate epicardial-specific Cre activity with tamoxifen induction at E10.5 and E12.5. Single administration of tamoxifen at E10.5 resulted in reporter gene (R26RT) expression in ~95% of epicardial cells after 24 hours (data not shown). Lineage tracing and in situ hybridization for Nf1 demonstrated that in Nf1 conditional embryos transcripts were reduced in the epicardium just 24 hours after induction (Fig. 1B), that epicardial cells were exclusively tagged, and that lineage-tagged cells migrated into the heart ventricles as expected (supplementary material Fig. S2A). The only other lineage-tagged regions were the atrioventricular valves, where epicardial cell contribution has been reported previously (de Lange et al., 2004). By contrast, at these time points of induction no lineage-tagged cells were detected in the cardiomyocyte population, nor in the semilunar valves (supplementary material Fig. S2B,C).

To specifically examine the role of Nf1 in the epicardium, we generated Nf1fl/fl;Wt1CreERT2/+ mice (referred to as Nf1WTiKO). We obtained the expected Mendelian ratios of animals and detected no overt phenotype in Nf1WTiKO animals, suggesting that epicardial inactivation of Nf1 by Wt1CreERT2 at E12.5 did not cause embryonic nor postnatal lethality (data not shown). Because we observed vimentin+ cells in the ventricles at time points earlier than expected (Fig. 1D), we examined whether premature EMT occurred upon loss of Nf1 by tracing the migration of epicardial cells labeled at E10.5. These hearts revealed that a substantial number of epicardial cells were present immediately below the basement membrane in Nf1WTiKO hearts, whereas tagged cells remained in the epicardium in controls (Fig. 1E). These data suggested that, in the absence of Nf1, epicardial cells migrate into the heart earlier than expected in all three genotypes examined (Nf1G5KO, Nf1fl/fl;Wt1CreGFP/+ and Nf1WTiKO).

**Loss of Nf1 results in spontaneous EMT of epicardial cells in vitro**

From the above data, we hypothesized that loss of Nf1 could result in accelerated EMT. First, we tested this possibility in vitro. We generated primary cultured epicardial cells from E12.5 hearts, which uniformly expressed the epicardial genes Tcf21 and Pdgfra (data not shown). After 3 days of culture, without any exogenous stimulus the control epicardial cells remained a cobblestone monolayer, whereas Nf1G5KO epicardial cells exhibited a mesenchymal morphology (Fig. 2A). We investigated two hallmarks of EMT, namely the loss of cell-cell contacts and the formation of actin stress fibers, by localization of β-catenin and vimentin.
filamentous actin, respectively. Control epicardial cells maintained cell-cell contacts, had extensive cellular junctions and exhibited cortical actin. However, Nf1<sup>G5KO</sup> epicardial cells formed extensive actin stress fibers and lost their junctions (Fig. 2B). These changes were inhibited by the Rho-associated protein kinase inhibitor Y27632 (Uehata et al., 1997), suggesting that known EMT signaling pathways were occurring in the Nf1<sup>G5KO</sup> mutant cultures (data not shown). These results also demonstrated a cell-autonomous role for Nf1 in regulating EMT.

Although morphology is commonly used as a readout for EMT, changes in gene expression profiles from epithelial to mesenchymal can also be used to detect the transition. We measured the expression of epithelial markers, such as Krt14 (Chamulitrat et al., 2003; Ke et al., 2008) and Bves (Wada et al., 2001), by qRT-PCR (Fig. 2C). Consistent with a switch from epithelial to mesenchymal cell type, we found that epithelial gene expression was downregulated in Nf1<sup>G5KO</sup> cultures. By contrast, mesenchymal gene expression, as indicated by Col7a1 (Vindevoghel et al., 1998), Mmp10 (Wilkins-Port and Higgins, 2007), Sox9 (Cheung et al., 2005; Sakai et al., 2006) and Opg (Tnfrsf11b – Mouse Genome Informatics) (Corallini et al., 2009; Sakata et al., 1999; Vidal et al., 1998), was upregulated (Fig. 2C). We also observed an increased level of mesenchymal gene expression in heterozygous cultures (data not shown).

An additional criterion for transition from an epithelial to a mesenchymal phenotype is invasion into a collagen gel (Thiery and Sleeman, 2006). In a collagen gel assay (Boyer et al., 1999; Potts et al., 1991), ~12% of control epicardial cells invaded the collagen gel along the edge of the culture (Fig. 2D,F). In Nf1<sup>G5KO</sup> epicardial cultures, ~60% of the cells in the same perimeter of the epicardial culture invaded the collagen gel and formed actin stress fibers (Fig. 2D,F).

When epicardial cells undergo EMT they differentiate predominantly into two cell types: cVSMCs and cardiac fibroblasts (Mikawa and Gourdie, 1996; Vrancken Peeters et al., 1999). To determine whether the increased EMT led to an increase in differentiated cells in vitro, we examined the expression of SM-MHC, a smooth muscle cell marker. Epicardial cultures from Nf1<sup>G5KO</sup> and to a lesser extent Nf1 heterozygous hearts exhibited an increased number of SM-MHC-expressing cells compared with control cultures (Fig. 2E,G).

In summary, Nf1 mutant epicardial cells spontaneously lost epithelial characteristics and adopted a mesenchymal phenotype, including an increase in mesenchymal gene expression, invasiveness and differentiation. It should be noted that loss of Nf1 resulted in EMT under basal culture conditions. Therefore, these cultured epicardial cells might be poised to undergo EMT, and signaling by Nf1 could be a key regulatory pathway inhibiting this process.

**Loss of Nf1 enhances EMT of epicardial cells in vivo**

To determine whether the loss of Nf1 has a direct effect on EMT, we induced temporal deletions of Nf1 between stages E10.5 and E12.5. These embryos therefore had wild-type expression of Nf1 until just before the stage of EMT. This tracing resulted in efficient R26<sup>R</sup> reporter expression in a high percentage of the epicardium (Fig. 3A). We then quantified the number of EPDCs that had migrated into the heart ventricle using whole-mount confocal microscopy at each time point. Fig. 3 is representative of optical sections comparing control and Nf1<sup>WTiKO</sup> hearts (see supplementary material Fig. S3 for images at other time points). The number of R26<sup>R</sup>-positive cells in the left ventricular region of the myocardial area (150 μm × 150 μm × 32 μm) was counted using ImageJ. Data are mean ± s.d. n values are indicated in parentheses. *P<0.0001; **P<0.0005.

Few R26<sup>R</sup>-positive cells were detected in the control myocardial compartment (Fig. 3A,B; supplementary material Fig. S3). Tagged epicardial cells were observed in the ventricle at E12.5 and further increased at E13.5, suggesting that EMT began at ~E12.5 in control hearts (Fig. 3B; supplementary material Fig. S3). However, in Nf1<sup>WTiKO</sup> hearts, at each time point examined a greater number of R26<sup>R</sup>-positive cells was detected within the myocardial compartment (Fig. 3A,B; supplementary material Fig. S3). The
Epicardial inactivation of Nf1 results in expansion of cardiac fibroblasts and cVSMCs in vivo

Because enhanced epicardial cell EMT and EPDC proliferation were observed, we reasoned that there might be an expansion of EPDCs. As cardiac fibroblasts and cVSMCs are the predominant populations of cells derived from the epicardium, we determined how loss of Nf1 impacted these cells. Using in situ hybridization for three genes that identify cardiac fibroblasts, namely Col1a1, Col3a1 and Pdgfra (Smith et al., 2011), we found an increased number of cardiac fibroblasts in mutant hearts compared with controls (Fig. 5A,C). Collagen I is also expressed by some VSMCs (Ponticos et al., 2004) and therefore it is likely that this particular probe overestimated the number of fibroblasts, but the data clearly demonstrated an increase in non-vessel-associated Col1a1-expressing, as well as Col3a1- and Pdgfra-expressing, cells. This increase in cell numbers was not restricted to the cardiac fibroblast lineage. We utilized the X-LacZ4Tg mouse (Tidhar et al., 2001) that expresses a nuclear-localized β-galactosidase in VSMCs and efficiently tags cVSMCs (Mellgren et al., 2008). We found that loss of Nf1 also resulted in an expansion of the VSMC lineage (Fig. 5B). Not only were more cVSMCs detected at E17.5, but the increase also appeared to lead to an extended and more highly branched cVSMC-coated network of coronary vasculature (Fig. 5D; data not shown).

Nf1 regulation of Ras signaling plays a role in PDGF-induced epicardial EMT

It is established that loss of Nf1 leads to prolonged activation of the Ras-MAPK pathway in cardiomyocytes and VSMCs (Cichowski and Jacks, 2001; Xu et al., 2009a; Xu et al., 2007). To determine whether activation of Erk1/2 (Mapk3/1 – Mouse Genome Informatics) is responsible for EMT in Nf1-deficient epicardial cells, we inhibited the MAP kinase pathway and measured EMT by ex vivo migration assay (Mellgren et al., 2008). The epicardium of E12.5 hearts was labeled by adenoviral GFP transduction, and migration of GFP-expressing epicardial cells into the myocardium was quantified. In control hearts, GFP+ cells were restricted to the epicardium (Epi) or myocardial ventricular wall (EPDC). Because enhanced epicardial cell EMT and EPDC proliferation was detected at E13.5 and E14.5, respectively, upon loss of Nf1 at E12.5, and heart sections were imaged for R26R fluorescent at E13.5 (A) or stained for β-galactosidase activity at E14.5 (C). In C, the boxed regions are shown at higher magnification in the insets. Arrowheads in A designate EPDCs expressing R26R. Scale bars: 100 µm. (B,D) Quantification of migrated R26R-positive or R26RlacZ-positive EPDCs in A and C, respectively. Images were taken from similar regions of heart in both left and right ventricles with a 40× or 20× field of view and counted for R26R-positive or R26RlacZ-positive cells within the myocardial ventricular wall. Data are mean ± s.d. n values are indicated in parentheses. *P<0.0001; **P<0.001; ***P<0.005. (E) Quantification of Wt1 lineage-tagged cellular proliferation. Embryos were maternally induced with tamoxifen at E12.5. Heart sections were stained for phospho-histone H3 (pH3) to detect mitotic cells. The pH3+ Tomato+ cells were counted in epicardial or myocardial regions and normalized to the total number of Tomato+ cells in epicardium (Epi) or myocardial ventricular wall (EPDC). Nuclei were visualized with DAPI for quantification and images were taken from similar regions of heart in both left and right ventricles with a 20× field of view. n values are indicated in parentheses. *P<0.01; **P<0.05; ns, no significant difference.

Fig. 4. Migration and proliferation of EPDCs after inactivation of Nf1 in vivo. (A,C) R26R (A) and R26RlacZ (C) epicardial lineage tracing was used to identify migrated epicardial cells in hearts of the indicated genotype. Induction with tamoxifen was at E12.5, and heart sections were imaged for R26R fluorescence at E13.5 (A) or stained for β-galactosidase activity at E14.5 (C). In C, the boxed regions are shown at higher magnification in the insets. Arrowheads in A designate EPDCs expressing R26R. Scale bars: 100 µm. (B,D) Quantification of migrated R26R-positive or R26RlacZ-positive EPDCs in A and C, respectively. Images were taken from similar regions of heart in both left and right ventricles with a 40× or 20× field of view and counted for R26R-positive or R26RlacZ-positive cells within the myocardial ventricular wall. Data are mean ± s.d. n values are indicated in parentheses. *P<0.0001; **P<0.001; ***P<0.005. (B) Quantification of WT1 lineage-tagged cellular proliferation. Embryos were maternally induced with tamoxifen at E12.5. Heart sections were in mitosis (Fig. 4E). At E13.5 we saw a modest increase in proliferation of Nf1-deficient epicardial cells (Fig. 4E). At the same stage, a similar number of the EPDCs in both control and mutant hearts were in mitosis (Fig. 4E). However, at later stages, Nf1-deficient EPDCs exhibited increased proliferation (Fig. 4E). Because alterations in cell survival have been reported in Nf1-deficient endocardial cushions (Lakkis and Epstein, 1998), we examined Nf1flox/flox and Nf1G5KO hearts for apoptosis, using an antibody for cleaved caspase 3, at various time points from E12.5 to P0. No differences in apoptotic cell numbers were observed between control and mutant hearts (data not shown).
number of GFP+ cells within the myocardium, suggesting an enhanced ability of Nf1-null epicardial cells to leave the epicardial layer (Fig. 6A,B). The increased migration was abolished when hearts were cultured in the presence of U0126, an inhibitor of both Mek1 and Mek2 (Map2k1 and Map2k2 – Mouse Genome Informatics) (Fig. 6A,B). These data suggest that activation of ERK is responsible for EMT in Nf1-deficient epicardial cells.

Loss of Nf1 alone does not lead to extended activation of Ras. Upstream signals are required to initiate Ras signaling, then in the absence of Nf1, Ras remains in its active state (McCormick, 1995). We have recently reported that PDGF receptor signaling is an essential component of epicardial EMT. Pdgfrα and Pdgfrβ are expressed in the epicardium, and inactivation of these receptors in epicardial cells disrupts EMT (Mellgren et al., 2008; Smith et al., 2011). To determine whether PDGF signaling could be one pathway upstream of Ras-Nf1 signaling, we inhibited PDGF receptor tyrosine kinase activity in Nf1-deficient epicardial cells. Imatinib mesylate, a potent inhibitor of both Pdgfrα and Pdgfrβ, inhibited the EMT phenotype caused by loss of Nf1 in the epicardial culture EMT assay (data not shown) and the ex vivo migration of epicardial cells (Fig. 6A,B). Similar results were obtained using AG1296, another inhibitor of the PDGF receptors (data not shown).

Next, we tested whether Nf1 Ras-GAP activity could negatively regulate PDGF-induced EMT in the ex vivo migration assay. Stimulation with recombinant PDGF-BB induced epicardial cell migration into the myocardium; however, adenoviral transduction of the Nf1 GAP-related domain (Nf1-GRD) (Hiatt et al., 2001; Miller et al., 2010) significantly reduced PDGF-BB-induced EMT (Fig. 6C,D). Conversely, we determined whether activation of Ras induced epicardial EMT using epicardial cultures from K-Ras(G12D)βi embryos. This transgene expresses a Cre-inducible oncogenic form of Kras (Jackson et al., 2001). Whereas control cultures had intact cellular junctions with cortical actin, when K-Ras(G12D) expression was induced the epicardial cultures formed actin stress fibers and lost cellular junctions, similar to Nf1-Wt1CreERT2/+ hearts (Fig. 6E). Similarly, K-Rasβi+/Wt1CreERT2/+ hearts had an increased number of Wt1+ cells in the myocardial compartment. This suggests that activation of Ras also results in increased epicardial EMT in vivo (Fig. 6F,G).

Finally, we determined whether loss of Pdgfrα signaling could partially rescue the excess EMT observed in the Nf1-Wt1CreERT2/+ heart. As loss of Pdgfrα specifically affects only cardiac fibroblast progenitor EMT (Smith et al., 2011), we predicted that loss of Pdgfrα in an Nf1-Wt1CreERT2/+ mutant background would lead to a reduction in EPDCs entering the epicardium as compared with an Nf1-Wt1CreERT2/+ mutant that possessed Pdgfrα signaling. Consistent with our previous data, Nf1-Wt1CreERT2/+ hearts had more Wt1+ cells within the myocardium than wild-type controls; however, simultaneous inactivation of both Pdgfrα and Nf1 resulted in a significant reduction of migrated Wt1+ cells (Fig. 6F,G). One reason for the partial rescue of the Nf1-Wt1CreERT2/+ EMT phenotype could be the presence of VSMC progenitors, which still express Pdgfrα (Mellgren et al., 2008; Smith et al., 2011) and should continue to have excess Ras signaling due to loss of Nf1.

In conclusion, our results show that Nf1 is a key regulator of epicardial EMT and that this increased EMT as well as an increased rate of proliferation result in expansion of cardiac fibroblasts and VSMCs.

**DISCUSSION**

EMT is an essential process that plays a significant role in embryogenesis during gastrulation, heart development and neural crest cell formation (Thiery et al., 2009). There is now very compelling evidence that EMT is an essential component of tumor metastasis (Thiery et al., 2009; Yang and Weinberg, 2008).
the best-known activity for Nf1 is its GAP activity, it is assumed that loss of Nf1 leads to abnormal Ras signaling. A further link with EMT can then be drawn because Ras signaling can induce EMT. One mechanism is by cooperating with TGFβ to promote Snail transcriptional activity (Horiguchi et al., 2009; Janda et al., 2002). Another is by activating MAPK and Rac, potentially leading to disruption of epithelial junctions (Edme et al., 2002). In fact, many of the EMT-inducing abilities of epidermal growth factor and hepatocyte growth factor have been directly linked to Ras activity (Boyer et al., 1997; Herrera, 1998). Here, we provide evidence that loss of Nf1 increases EMT in mouse epicardial cells, suggesting a possible regulatory role for Nf1 in Ras-driven EMT.

Interestingly, loss of Nf1 does not lead to persistent EMT. Instead, the EMT we observed is only amplified by occurring temporally, thus providing an explanation for why epicardial EMT in the absence of Nf1 is still partially restricted. Indeed, we have shown that by inhibiting one of these potential upstream growth factor pathways, i.e. PDGF (Mellgren et al., 2008; Smith et al., 2011), we can block the effects of loss of Nf1. Interestingly, increased neointima formation in Nf1 heterozygous mice can also be mitigated by imatinib treatment, suggesting a possible role for PDGF signaling in the exaggerated vascular injury response that occurs upon the loss of Nf1 (Lasater et al., 2008). Because inhibition of MAPK also blunted the effect of loss of Nf1 on EMT, it is likely that Nf1 attenuates these inductive signals only in the epicardial cells that have been stimulated to undergo EMT.

Cardiovascular disease is a frequent cause of death in patients with neurofibromatosis I who are less than 30 years old (Rasmussen et al., 2001). Although some of this lethality is attributed to congenital abnormalities (Friedman et al., 2002; Lin et al., 2000), our findings also point to the possibility that an increase in the proliferation of epicardial-derived noncardiomyocyte lineages might also contribute to some of the heart abnormalities. Loss of Nf1 did not lead to excessive overgrowth of these cells under normal circumstances. It is likely that local environmental cues ultimately determine the differentiation and survival of EPDCs. For example, endothelial cells, which secrete PDGF ligands, are important regulators of
cVSMC migration and proliferation (Tomanek, 2005). Similarly, local limitations of growth factor production by these cells might account for the lack of excessive cVSMC proliferation. Therefore, loss of Nf1 results in a controlled expansion of EPDC's rather than massive hyperplasia. This phenomenon would be reminiscent of what occurs with Nf1-mediated tumorigenicity, in which disruptions in the microenvironment are necessary for tumor progression (Zhu et al., 2002). Nonetheless, because loss of Nf1 is often linked to increased proliferation (Lynch and Gutmann, 2002) during a pathological response to heart injury, Nf1-deficient cells might respond more robustly by enhanced proliferation and fibrotic activity. Most neurofibromatosis 1 patients would be haploinsufficient in somatic cells, but our data and those of others suggest that even cells with reduced Nf1 protein might have elevated levels of GTP-bound Ras, thus leading to increased signaling and downstream cellular events (Atti et al., 1999; Ingram et al., 2000).

In summary, we demonstrate that epicardial loss of Nf1 results in early and increased EMT, which leads to the expansion of cardiac fibroblasts and cVSMCs. We were able to mitigate the increased EMT by altering PDGF signaling, which has recently been implicated in epicardial EMT (Smith et al., 2011). Our work indicates that EPDCs, along with endocardial-derived valve cells and cardiomyocytes are sensitive to perturbations in Nf1 activity. Further investigations will be required to determine what the long-term outcomes of this EPDC expansion are for the physiology of the heart under pathological and non-pathological conditions.

Acknowledgements
We thank Ray Runyan for essential comments and help with the collagen gel invasion assay; Moshe Shani for providing the X-LacZ tissue line; Nancy Ratner for providing Nf1-GRD adenovirus; Christopher Smith and other M.D.T. laboratory members for scientific discussion and critical reading of the manuscript; and Greg Urquhart, Banu Eskiocak and Emily Webster for technical assistance.

Funding
This work was supported by National Heart, Lung, and Blood Institute (NHLBI) grants from the National Institutes of Health [HL074257 and HL100401 to M.D.T.]; and an American Heart Association Predoctoral Fellowship [10PRE3730051 to S.T.B.]. Deposited in PMC for release after 12 months.
