ABSTRACT

Polysaccharides are major components of extracellular matrices and are often extensively modified post-synthetically to suit local requirements and developmental programmes. However, our current understanding of the spatiotemporal dynamics and functional significance of these modifications is limited by a lack of suitable molecular tools. Here, we report the development of a novel non-immunological approach for producing highly selective reciprocal oligosaccharide-based probes for chitosan (the product of chitin deacetylation) and for demethylsterified homogalacturonan. Specific reciprocal binding is mediated by the unique stereochemical arrangement of oppositely charged amino and carboxy groups. Conjugation of oligosaccharides to fluorophores or gold nanoparticles enables direct and rapid imaging of homogalacturonan and chitosan with unprecedented precision in diverse plant, fungal and animal systems. We demonstrated their potential for providing new biological insights by using them to study homogalacturonan processing during Arabidopsis thaliana root cap development and by analyzing sites of chitosan deposition in fungal cell walls and arthropod exoskeletons.

KEY WORDS: Polysaccharides, Arabidopsis, Exoskeletons, Carbohydrate microarrays, Cell wall, Fluorescence imaging, Root cap

INTRODUCTION

Many organisms produce polysaccharide-rich extracellular matrices, including the cell walls of plants and fungi, and the exoskeletons of arthropods. Homogalacturonan (HG) is a major structural feature of the pectic polysaccharides that are present in plant cell walls; it provides structural support, mediates cell adhesion, regulates wall porosity and generates a dynamic operating environment for other cell wall components (Caffall and Mohnen, 2009; Willats et al., 2001). HG is a linear polysaccharide composed of α-(1→4)-linked D-galacturonic acid residues, which can be methyl esterified at C-6 (Caffall and Mohnen, 2009). HG is frequently subject to post-synthetic demethylsterification in the cell wall by pectin methylesterases (PMEs), and the degree of methyl esterification and the distribution of remaining ester groups profoundly impacts upon the functional properties of HG (Wolf et al., 2009). Plants typically produce dozens of PMEs, enabling them to fine-tune these functional properties in muro with exquisite precision within cell wall microdomains (Pelloux et al., 2007). The spatiotemporal regulation of PME activities is one of the key downstream components of many plant developmental pathways that determine growth and development, and responses to biotic and abiotic stresses (Wolf et al., 2009, 2012; Peaucelle et al., 2008; Peaucelle et al., 2011a; Peaucelle et al., 2011b; Ferrari et al., 2013).

Chitin, a polymer of β-(1→4)-linked N-acetylglucosamine is the main constituent of the exoskeletons of arthropods and of fungal cell walls, and may be deacetylated by chitin deacetylases (CDAs) to produce chitosan (Eijssink et al., 2010; Tsigos et al., 2000). Analogous to methyl esterification of HG, the degree of acetylation has important functional implications. In many cases, the biological significance of chitin acetylation state is poorly understood, but the quantity and ratio of chitin to chitosan is highly dynamic depending on the developmental phase and cellular interactions (Christodoulidou et al., 1999; Baker et al., 2011; Heustis et al., 2012; Lasnbig et al., 2006; Wang et al., 2006). For example, tracheal tube elongation in Drosophila melanogaster is regulated by luminal CDA proteins (Lasnbig et al., 2006; Wang et al., 2006).

Understanding the developmental roles and cellular processing of structural polysaccharides such as HG and chitosan requires specific detection of them in situ and, preferably, in vivo. Monoclonal antibodies (mAbs) and carbohydrate binding modules have been widely used as probes, but these large proteinaceous molecules have considerable limitations in terms of penetration and suitability for live- and real-time labelling (Verhertbruggen et al., 2009; McCartney et al., 2006). Other advanced labelling procedures, such as the use of sugars attached in vivo through click chemistry, are powerful but time consuming and technically challenging (Anderson et al., 2012).

It is known that chitosan oligosaccharides (COS) can modulate the biological activity of oligogalacturonate (OGA) fragments of HG (Cabrera et al., 2010), and our molecular modelling of the COS and OGA interaction confirmed that their reciprocal binding is mediated by the precise alignment of the positively charged amino groups on COS and the negatively charged carboxyl groups on OGA (Fig. 1A). We exploited this natural affinity to develop oligosaccharide-based reciprocal probes for de-esterified HG and chitosan (Fig. 1B). These probes have several desirable features when compared with the use of antibodies: they are very rapid to use and easy to couple directly to a variety of tags; furthermore, their small size allows high-resolution

imaging and effective tissue penetration. Moreover, unlike antibodies, they are suitable for direct real-time imaging of polysaccharide processing.

RESULTS

Testing of COS<sub>488</sub> and OGA<sub>488</sub> reciprocal specificity using microarrays of defined glycans

COS and OGA samples (supplementary material Fig. S1) were coupled to aminooxy-functionalyzed Alexa Fluor fluorophores or to gold nanoparticles (Fig. 1B). To assess the binding specificities of these conjugates, we utilized carbohydrate microarrays (Pedersen et al., 2012) populated with 41 defined oligo- and polysaccharides. The arrays included pectin samples that had been treated with PMEs to produce HG with progressively lower degrees of methyl esterification. The COS probe coupled to Alexa Fluor 488 (COS<sub>488</sub>) bound to HG-containing pectic polysaccharides and to OGAs, but not to other oligo- or polysaccharides. Importantly, no binding to bovine serum albumin (BSA) or the polyanionic polysaccharides chondroitin sulphate A and B was observed (Fig. 1C; supplementary material Fig. S2). As expected, COS<sub>488</sub> binding to the pectic polysaccharides was positively correlated with decreasing degrees of methyl esterification, and to the oligosaccharides with increasing degrees of polymerization. In the case of oligosaccharides, the strongest binding was detected for octagalacturonate, weaker binding for heptagalacturonate and pentagalacturonate, and no binding for shorter OGAs (Fig. 1C; supplementary material Fig. S2). Using the same approach, we also characterized the reciprocal probe, OGA coupled to Alexa Fluor 488 (OGA<sub>488</sub>). As predicted, this probe bound to chitosan and, more weakly, to partially acetylated chitosan but not to fully acetylated chitohexaose or any other oligo- or polysaccharides (Fig. 1C; supplementary material Fig. S2). These data indicate that COS and OGA are highly selective probes for non-methyl esterified HG and chitosan, respectively.

Only one antibody against chitosan has been reported (Sorlier et al., 2003), but several mAbs against HG have been described previously in detail (Verhertbruggen et al., 2009), and we compared their binding to that of COS<sub>488</sub>. COS<sub>488</sub> binding was distinct from that of the seven mAbs against HG tested and was more selective towards sparsely methyl esterified pectins (supplementary material Fig. S2). As expected, COS<sub>488</sub> binding to the pectic polysaccharides was positively correlated with decreasing degrees of methyl esterification, and to the oligosaccharides with increasing degrees of polymerization. In the case of oligosaccharides, the strongest binding was detected for octagalacturonate, weaker binding for heptagalacturonate and pentagalacturonate, and no binding for shorter OGAs (Fig. 1C; supplementary material Fig. S2). Using the same approach, we also characterized the reciprocal probe, OGA coupled to Alexa Fluor 488 (OGA<sub>488</sub>). As predicted, this probe bound to chitosan and, more weakly, to partially acetylated chitosan but not to fully acetylated chitohexaose or any other oligo- or polysaccharides (Fig. 1C; supplementary material Fig. S2). These data indicate that COS and OGA are highly selective probes for non-methyl esterified HG and chitosan, respectively.

Fig. 1. Reciprocal binding of oligogalacturonates and chitosan oligosaccharides. (A) Molecular model showing the conformational features of oligogalacturonate (OGA) and chitosan oligosaccharides (COS) that promote binding by the alignment of opposing charges of the carboxyl groups on OGA and amino groups on COS. The numbers indicate the distance in Angstroms (Å) between carboxylate carbon atoms (on OGA) and ammonium group nitrogen atoms (on COS) after minimization. (B) Schematic showing the charge-based binding of COS and OGA to homogalacturonan (HG) with a low degree of methyl esterification (DE) and chitosan, respectively. Binding sites are created by pectin methylsterases (PME) and chitin deacetylases (CDAs) acting on HG and chitin to form de-esterified HG and chitosan, respectively. Directly tagged COS and OGA probes were produced through coupling to a range of fluorophores or nanogold particles. The probes were named according to their tag; hence, a COS probe coupled to Alexa Fluor 488 is designated COS<sub>488</sub> and COS coupled to nanogold particles is COS<sub>AuNP</sub>. For MALDI-ToF analysis of COS and OGA, see supplementary material Fig. S1 and methods in the supplementary material. (C) The binding specificity of COS<sub>488</sub> and OGA<sub>488</sub> was tested by probing carbohydrate microarrays that were populated with the oligo- and polysaccharides listed, including lime pectins, with a range of degrees of methyl esterification. Numbers indicate normalized mean of spot signals obtained from microarrays. Colour intensity is correlated to signal strength. For more extensive specificity analysis and comparison with antibodies against HG, see supplementary material Fig. S2.
bound to DNA on arrays, whereas COS\textsuperscript{488} binding to DNA was very weak (supplementary material Fig. S2).

Detection of HG in diverse plant species using COS conjugates

We tested whether COS\textsuperscript{488} could be used to directly visualize HG in a variety of plant systems (Fig. 2). Rapid (<20 min) labelling was possible by directly immersing the samples into a COS\textsuperscript{488}-containing solution for a short time, followed by a brief washing step (Fig. 2A). HG-specific labelling was confirmed by using a set of controls that demonstrated the reduction of the labelling signal following treatment with polygalacturonase (supplementary material Fig. S3A-D). By using COS\textsuperscript{488} in conjunction with mAb JIM7 (Verhertbruggen et al., 2009), which recognizes highly methyl esterified HG, we were able to observe the cellular location of HG with different esterification states within discrete cell wall microdomains in \textit{Arabidopsis} stem parenchyma cells (Fig. 2B-F). When initially synthesized and deposited in cell walls, HG typically had a high degree of methyl esterification, as shown by the labelling of JIM7 on the plasma membrane face of cell walls (Fig. 2B). Demethylated HG, produced by the activity of extracellular PMEs, is typically located between cells, where it is required for cell adhesion (Willats et al., 2001). Consistent with this, binding of COS\textsuperscript{488} was restricted to the corners of intercellular spaces and middle lamellae (Fig. 2C,E,F). Using COS\textsuperscript{488}, we also investigated the spatiotemporal distribution of HG in green algae, which often display highly dynamic HG post-synthetic modifications (Sørensen et al., 2011). In the charophyte alga \textit{Micrasterias furcata}, at a late stage of cell division, COS\textsuperscript{488} labelled punctate structures on the surface of the growing daughter semi-cell, but not the mother semi-cell (Fig. 2G). By contrast, the mother semi-cell, but not the daughter semi-cell was labelled with JIM7, which binds to HG that has a high degree of methyl esterification (Fig. 2G). Labelling of whole cells of the multicellular \textit{Spirogyra sp}, with COS\textsuperscript{488} revealed demethylated HG that was present at the tips of growing cell outgrowths. Labelling was also strong at the junction planes between cells, and this is important because it suggests that the role of HG in cell adhesion emerged early in green plant evolution (Fig. 2H). The unicellular alga \textit{Penium margaritaceum} is covered in a highly intricate pectin-rich lattice with projections (Fig. 2I). Labelling of \textit{P. margaritaceum} demonstrated that the small size of the COS and OGA probes compared with that of antibodies (approximately 1.7 and >150 kDa, respectively) provided superior image resolution. Using COS\textsuperscript{488}, this network was clearly resolved with particularly strong labelling of spine-like projections (Fig. 2J). Probing with the antibody JIM5 (against HG) produced a similar overall labelling pattern, but the resolution was apparently lower than that obtained using COS\textsuperscript{488} (Fig. 2K). Moreover, using COS coupled to nanogold particles (COS\textsuperscript{AuNP}) in conjunction with transmission electron microscopy enabled us to locate HG at the ultrastructural level (Fig. 2L; supplementary material Fig. S3E,F).

The \textit{Arabidopsis} root cap is a hotspot for HG de-esterification

The \textit{Arabidopsis} root tip is a widely used developmental model in plant biology, and we analyzed HG distribution and turnover during root cap development using the COS probe (Fig. 3). As the outermost layer of the root cap matures with time, it is usually sloughed as a file of cells, sometimes called border-like cells. This is a cyclic event that protects the root proper during penetration through the soil (Bennett et al., 2010; Driouich et al., 2007; Fig. 3A,B). Many aspects of the cellular processes underlying root cap maturation, including cell wall turnover, are poorly understood, although a regulatory role for NAC transcription factors has been demonstrated previously (Bennett et al., 2010).

were analyzed in each. Scale bars: 10 μm.

...in 83% of cases (three independent experiments, at least eight roots per sample). This pattern was observed in both the mature layer of root cap and in the inner regions. This pattern was similar to that observed in Arabidopsis root cap regions. (D,E) Labelling of resin sections by using mAbs against HG, JIM5 (D) and JIM7 (E). (F,G) Whole-mount labelling of the root tip using COS647. Note the labelling pattern is similar to that observed in resin sections. (F) The lateral root cap region and (G) the columella region. Note the sloughing cell layer (arrowhead). Inc, lateral root cap; ep, epidermis; co, columella. (H-K) Time-lapse experiment using two fluorescent variants of the COS probe. Seeding seeds were first labelled using COS647 (red), washed and allowed to grow for 4 h. Seedlings were then re-labelled with COS488 (green) and washed. The simultaneous scan of (H) COS647 and (I) COS488 labelling at the end of the experiment. (J) The overlay image shows the differences between the initial and the freshly formed HG with a low degree of methyl esterification. (K) Fluorescence plot profile of the two signals from H and I, the plot position is indicated as the dashed line in J. Note the higher accumulation of the COS488 signal (freshly formed epitopes) in the cell walls of the mature layer of root cap than in the inner regions. This pattern was seen in 83% of cases (three independent experiments, at least eight roots were analyzed in each). Scale bars: 10 μm.

The high penetrative capacity of COS488 made it a promising tool in order to study the role of HG in this process, and when whole unfixed Arabidopsis roots were immersed in COS488, labelling was clearly observed at least three cell layers in from the epidermis. By contrast, the mAbs JIM5 and JIM7 (Verbernebruggen et al., 2009) did not penetrate the epidermal cell layer (supplementary material Fig. S4A-D,G). We also produced longitudinal thin sections of resin-embedded root tips (Fig. 3C-E; supplementary material Fig. S4E,F). Labelling of these sections with COS488 indicated that de-esterified HG appeared to be especially abundant in mature root cap cells (Fig. 3C). We also compared this pattern of staining with that of the mAbs JIM5 and JIM7. JIM5 labelling of HG was more pronounced in the mature lateral root cap but largely absent from the columella (Fig. 3D), whereas the JIM7 signal was uniformly distributed across the root tip with no obvious enrichment in the mature root cap layer (Fig. 3E). Because they are loosely attached, the mature root cap cells tend to be lost during resin embedding. By contrast, whole-mount in vivo labelling of intact root tips and then using COS488 enabled observation of these cells during the process of detachment (Fig. 3F,G). It was notable that the cell walls of the root cap cells become thicker during maturation (supplementary material Fig. S4E-G). We measured the signal intensities of JIM5, JIM7 and COS488 across the root tip and found that the signals increased for all three probes, but the increase was greater for JIM5 and COS488 than that for JIM7. These observations indicated that the increased signals were not merely a function of greater wall thickness in mature root cells and that the occurrence of HG, especially with a lower degree of methyl esterification, was elevated in outer root cap cells (supplementary material Fig. S4E-G).

**Time-lapse labelling experiments to visualize HG dynamics in root cap**

The root labelling experiments suggested that HG demethylsterification could be a distinctive feature of these cells related to their particular functional characteristics, and we further investigated this using a time-lapse experiment that exploited the live-labelling potential of the COS probes (Fig. 3H-J; supplementary material Fig. S5A-C). This experiment would not be feasible using mAbs because of the incompatibility between the conditions required for root growth and mAb binding. The basis of the experiment was to use two fluorescent variants of COS sequentially to distinguish original and newly generated HG epitopes within a relatively short time period (4 h). To accomplish this, we generated another fluorescent variant of COS conjugated to Alexa Fluor 647 (COS647), which had the same penetrative capacity and labelling pattern as COS488 (supplementary material Fig. S5B,C). First, we labelled the seedlings with COS647, then washed out the probe and let them grow for 4 h, and then re-labelled them with COS488. Initial labelling with COS647 identified original demethylsterified HG (Fig. 3H), whereas the second labelling with COS488 identified the demethylsterified HG that had freshly formed in the intervening 4 h period (Fig. 3I). The composite overlay image of the two labels indicated that the greatest abundance of newly formed demethylsterified HG was located in mature root cap cells (Fig. 3J,K). Importantly, the same result was also achieved in the reverse order, using first COS488 and then COS647; therefore, this effect was not due to the different properties of the COS conjugates (supplementary material Fig. S5D-H).

**Several PME and PMEI-like genes are specifically expressed in the root cap**

Because COS labelling experiments suggested a role for enhanced PME activity in root cap cells, we reviewed the expression profiles of PMEs and related genes in publically available microarray transcriptome databases. This showed that several PMEs and...
PMEI enzymes exhibited strong and specific expression patterns in root cap cells (supplementary material Fig. S6). We confirmed this pattern for two PME- and PMEI-like genes by generating GUS reporter lines. Importantly, expression of both genes was upregulated in the mature layer of the root cap (Fig. 4A,B), suggesting that root cap maturation is indeed a hotspot of HG esterification processing through the activity of PMEs.

Consequences of the loss of COS$^{488}$ binding sites in mature root cap cells

We also investigated the physiological role of HG de-esterification in the root cap. We did not observe any phenotypic variation in the transfer (T)-DNA insertion mutants of the respective PME genes compared with the phenotype of wild-type plants, and one probable explanation for this is the known high level of genetic redundancy of PMEs (Pelloux et al., 2007; Wolf et al., 2009). To overcome this, we employed a systemic chemical inhibitor of PMEs, (-)-epigallocatechin gallate (EGCG) (Lewis et al., 2008; Wolf et al., 2012), which targets PME activity in vivo. We treated seedlings with EGCG for 4 h at a concentration of 200 μM (this concentration did not completely inhibit root growth) or by directly supplementing EGCG to Murashige-Scoog agar plates at a concentration of 100 μM for continuous growth inhibition. Following treatment, the roots were labelled with COS$^{488}$, JIM5 and JIM7, confirming that EGCG did indeed inhibit the formation of demethyl-esterified HG, whereas the highly methyl esterified HG was unchanged (Fig. 5A,B; supplementary material Fig. S5I). Inhibition during the pulse experiment was more pronounced than that upon continuous growth on EGCG, which further supports the notions that a feedback signalling loop exists (Wolf et al., 2012) and that the upregulation of some PMEs might partially diminish the inhibitory effect of EGCG (Fig. 5B). Next, we investigated the diminution of HG synthesis through COS$^{488}$ labelling of quasimodo1 and quasimodo2 mutants, which are defective in galacturonosyltransferase and methyltransferase activity, respectively (Bouton et al., 2002; Mouille et al., 2007). Both mutants have an HG content of approximately 50% of that in wild-type plants. Their characteristic phenotype is that of being defective in cell adhesion (Bouton et al., 2002; Mouille et al., 2007) with altered organization of border-like cells (Durand et al., 2009). The binding of COS$^{488}$ to both quasimodo mutant roots was substantially reduced, as was the case with treatment with EGCG (Fig. 5A,B), confirming that both HG synthesis and the activity of PME are responsible for the formation of COS$^{488}$-binding epitopes.

The effect of EGCG on root cap physiology was further examined by growing seedlings on plates containing three concentrations of EGCG. We observed that treatment with EGCG resulted in the retention of root cap cells in a dose-dependent manner, such that...
multiple layers of cells accumulated rather than being sloughed off (Fig. 5C,D). Interestingly, although quasimodo mutants and EGCG-treated plants both showed reduced binding of COS488, the effects on root cap cell separation were different. Although EGCG-treated plants exhibited root cap cell retention, this was not the case for the quasimodo mutants, in which we observed instances of premature separation (Fig. 5C). Thus, although reduced HG synthesis and the inhibition of PME activity are both characterized by the diminution of COS488 epitopes, the physiological consequences are distinct. Taken together, these data provide new insights into the role of PMEs and HG turnover in root cap maturation, and demonstrate the potential of COS-based probes as powerful new tools for studying the developmental role of HG in planta.

Detection of chitosan in fungal cells using OGA488

Next, we tested whether the OGA-based probe OGA488 could be used for chitosan detection in fungal model species (Fig. 6; supplementary material Fig. S7). Saccharomyces cerevisiae spores are known to have a cell wall structure that differs from that of diploid cells in that they possess a chitosan layer (Christodoulidou et al., 1999). Consistent with this, OGA488 labelled the tetrad of spores inside asci, but did not label diploid cell walls (Fig. 6A). In another model fungi, Neurospora crassa, OGA488 binding was restricted to septa between cells (Fig. 6B; supplementary material Fig. S7A,B). Chitosan production has also been implicated in fungal pathogenesis (Baker et al., 2011), and we explored this in the context of host-parasite tissue interactions in the housefly Musca domestica that had been infected with the pathogenic fungus Entomophthora schizophorae. This fungus grows inside the fly haemocoel before corrupting host behaviour and inducing the fly to move to an elevated position where it attaches itself to the substrate and eventually dies (Roy et al., 2006). The fungus then grows out through the membrane between the sclerotized segments of the abdomen to produce new infectious spores. OGA488 only labelled fungal structures and not fly tissue, and revealed that chitosan was exclusively located in the conidiophore cell walls emerging between the abdominal sclerites of the fly (Fig. 6C; supplementary material Fig. S7C-F).

OGA488 as a tool to study the exoskeletons of arthropods

Finally, we used OGA488 to probe for chitosan in arthropod species. Whole-mount labelling of adult Drosophila flies revealed that chitosan localized in the tarsal knee joints, with a higher abundance in the socket of the joint (Fig. 7A-D; supplementary material Fig. S8A-J). To confirm that this apparently restricted localization of chitosan was not simply owing to limited access in the whole-mount material, we also probed sections of resin-embedded material (supplementary material Fig. S8G-J). As expected, the leg exoskeleton was evenly labelled throughout by the chitin stain...
Calcofluor, whereas the OGA^{488} signal was still restricted to tarsal knee joints. To further validate that the epitope recognized by OGA^{488} was indeed chitosan, we treated some samples with chitosanase and some we re-acetylated using pyridine-acetic anhydride. In both cases, the binding of OGA^{488} was greatly diminished (supplementary material Fig. S8F,G). Moreover, we also performed chemical deacetylation of all chitin that was present in the legs of D. melanogaster using concentrated NaOH (Kurita et al., 1991). This treatment converts chitin to chitosan, and as expected resulted in strong OGA^{488} labelling in the whole leg cuticle (Fig. 7A-D, bottom panels). Thus, treatment with NaOH followed by OGA^{488} labelling is an efficient way to detect chitin per se, and we demonstrated this approach on small fresh water crustaceans Cyclops sp. and Dafnia pulex, in which the majority of the exoskeleton is constructed of chitin (Fig. 7E-F; supplementary material Fig. S8K-Q). In Cyclops sp., chitosan only occurs in a region of the segmented body and in the tail appendages (supplementary material Fig. S8L). After NaOH deacetylation, OGA^{488} labelled the entire exoskeleton (Fig. 7E; supplementary material Fig. S8N). Similarly, OGA^{488} labelling of untreated Dafnia pulex exoskeletons showed only weak signals, but after deacetylation the whole specimen was brightly stained, which was again lost after chemical re-acetylation (Fig. 7F; supplementary material Fig. S8O-Q).

**DISCUSSION**

By exploiting their unique physicochemical properties, we have developed a new class of molecular probes for HG, chitosan, and in combination with sodium hydroxide pre-treatment, also chitin. These new tools address significant analytical deficiencies and have several distinct advantages over antibodies: one-step labelling is rapid and simple, their small size ensures excellent tissue penetration and high resolution, and the ease of direct conjugation to a variety of tags facilitates dual labelling and time course experiments. An important additional feature is that, unlike antibodies, these probes are not optimized for use at the mammalian physiological pH of around 7. This is especially important in the case of plant research because most antibodies are not compatible with plant growth conditions (usually less than pH 5.7) and therefore cannot be used for live-labelling studies. This is a serious limitation because it means that HG localization studies have been largely confined to dead, sectioned plant materials without the possibility to investigate the often rapid and highly dynamic processes associated with HG synthesis and processing.

The epitope and paratope interactions that govern the binding of conventional hybridoma-based mAbs are generally mediated by a variety of non-covalent bonds, and this contribution from multiple forces might explain why relatively subtle variations in the degree of methyl esterification are not sufficient to define specificity in these mAbs. This is especially true for the most commonly used probe against HG, mAb JIM5, which binds to HG with a relatively broad range of degrees of methyl esterification (supplementary material Fig. S2). By contrast, because binding of COS and OGA probes appears to be entirely mediated by ionic interactions and particular molecular stereochimistry, they are highly sensitive to changes in methylation and acetylation status; thus, they are well suited to study chitin and HG synthesis, and subsequent processing by PMEs and CDAs.

The study of Arabidopsis root tips demonstrated the potential of the COS probe for tracking HG turnover in vivo. Our data indicated that, in Arabidopsis root cap cells, the inhibition of demethylsterification, as well as lower levels of HG synthesis, resulted in a reduction of COS binding sites with some distinct cellular consequences. HG with a low degree of methyl esterification has been associated with the formation of Ca^{2+}-crosslinked ‘egg box’ structures that are generally considered to promote cell-to-cell adhesion (Fig. 2C). Consistent with this, loss or reduction of HG synthesis leads to defects in cell adhesion, as seen in the quasimodo mutants (Bouton et al., 2002; Mouille et al., 2007). Conversely, removal of methyl esters also creates cleavage sites for certain HG-degrading enzymes, for example polygalacturonases, that act to disassemble HG networks and promote cell separation (Rhee et al., 2003; Francis et al., 2006; Ogawa et al., 2009). This might explain the reduced cell separation defect after PME inhibition by EGCQ. However, the pectin degrading activity during separation should be apparent through the loss of the COS signal. In fact, we observed strong COS labelling before and after separation in mature root cap cells (Fig. 3F,G). One explanation for this intriguing finding is that in these cells, which are subjected to an unusual degree of mechanical stress, Ca^{2+}-crosslinked HG plays a primary role in cell wall stiffening rather than adhesion. If Ca^{2+}-crosslinked HG is used for this purpose, it might limit the formation of egg box structures that are available between the cells. Partial loss of PME activity would make more HG available in middle lamellae than usual and would explain the observed phenotypes in the EGCQ-treated seedling. Taken together, our findings demonstrate that HG methylation is fine-tuned at the cellular level and provide evidence for a possible new and subtle aspect of this regulation operating in a subset of root cells.

OGA probes appear to be powerful new tools for studying chitosan deposition in opisthokonts, and we newly identify several instances of restricted chitosan production in model organisms. Additional genetic and physiological experiments would be necessary to fully understand the biological roles of chitosan, but some insight into functionality can be inferred from its known physicochemical properties (Rinaudo, 2006) and the localization experiments described here. For example, chitosan in the sporangiophores of E. schizophorae might facilitate the hydration of the fungal tissue after exiting the host environment, and the chitosan in tarsal joints might play a role in lubrication. This notion is supported by the fact that silencing of a CDA gene in the beetle Tribolium castaneum results in impaired articulation of tibial-femoral joints in adult animals (Arakane et al., 2009).

In conclusion, we believe that OGA- and COS-based probes have the potential to shed new light on the numerous subtle and dynamic processes that are associated with chitin and HG post-synthetic developmental regulation. Because the properties that promote reciprocal binding are particular to COS and OGA, the potential for extending this general concept to other oligosaccharides could be limited. Nevertheless, the glycan microarrays we used for this study would be well suited to screening large chemical libraries, and new candidates might emerge using this approach.

**MATERIALS AND METHODS**

**Sourcing and growth of plant, animal and fungal materials**

Penium marrgitarameum, Mircasterias furcata andSpirogyra sp. were grown in sterile liquid Woods Hole Medium (WHM) at 18°C under 2000 lux of cool white fluorescent light with a 16 h light:8 h dark photoperiod. Cells were collected by using centrifugation and then washed three times with WHM before labelling or experimental treatment. Arabidopsis thaliana Col-0, Ws, qua1-2 (Bouton et al., 2002), qua2-1 (Mouille et al., 2007) and tobacco plants were grown in a greenhouse (long day, 22°C). Arabidopsis seedlings were grown on vertical Murashige-Scoog plates with 1% sucrose in a growth chamber (long day, 21°C). To create the GUS reporter lines, the genomic
fragment of At2g21610, including 1385 bp of the promoter region, and the promoter region of At4g00080 (1385 bp upstream of ATG) were amplified and cloned into pGWB3 (Nakagawa et al., 2007) using Gateway technology (Invitrogen). The resulting constructs were transformed by using the Agrobacterium-mediated floral dip method to Col-0 plants. The GUS staining was performed as described previously (Benková et al., 2003). Saccharomyces cerevisiae strain BY4743 was cultivated on yeast peptone dextrose (YPD) plates, and the sporulation was performed as described previously (Elrod et al., 2009). Neurospora crassa FGS no. 2489 was grown on potato dextrose agar plates. Drosophila melanogaster strain Oregon-R-S was cultivated in standard conditions on cornmeal media, anaesthetized with ether and fixed in 70% ethanol. Cyclops sp. was collected in a local pond and Daphnia pulex was obtained from a shop selling aquarium supplies. Entomophthora schizophorae was cultivated by consecutively infecting adult houseflies, Musca domestica, by placing sporulating fly cadavers over small plastic cups covered with insect netting and allowing Musca domestica supplies. Entomophthora schizophorae in a local pond and Oregon-R-S was cultivated in standard conditions on cornmeal media, Saccharomyces cerevisiae staining was performed as described previously (Benková et al., 2003).

8 μM EGCG, and then incubated for 30 min. The nanoparticles were then purified by filtration through 10 kDa molecular mass cut-off filters (Nanosep 10 K Omega) and washed three times with 400 μl of water. The particles were then collected from the filter in 100 μl of water. Negative controls (ethanolamineAuNP and linkerAuNP) were produced in an identical fashion by reacting the nanogold particles with ethanolamine (1 μl) or the linker (1 mg) under the same reaction conditions.

**Carbohydrate microarrays of oligo- and polysaccharides**

Carbohydrate microarrays were produced, probed with antibodies and quantified as described previously (Pedersen et al., 2012). For probing with COS and OGA probes, the arrays were blocked with 5% skimmed milk in MES buffer pH 5.7 for 30 min followed by three washes with MES buffer. COS and OGA were applied to arrays for 15 min, diluted 1 in 1000 in MES buffer. After washing three times, each for 10 min, with MES buffer, the arrays were dried prior to scanning (GenePix 4400) and quantified as described previously (Pedersen et al., 2012).

**Transmission electron microscopy of Penium margaritaceum cell walls using COSAuNP**

Centrifugation was used to collect 7-day-old cultures of P. margaritaceum, washed and spray-frozen in liquid propane as previously described (Domozhyl, 1999). The cells were then freeze substituted in 0.5% glutaraldehyde with acetic for 48 h at −80°C. The cells were warmed to −20°C, washed with cold acetone and then infiltrated and embedded in London Resin at −20°C. Polymerization was by UV light over 16 h at −20°C. C. Sections (50-70 nm) were obtained using a Leica Ultracutomicrotome and collected on formvar coated nickel grids. The sections were incubated for 2 h at room temperature or overnight at 4°C in either 1 μg/ml COSAuNP or ethanolamineAuNP or ethanolamineAuNP or linkerAuNP. The sections were then washed extensively with deionized water, fixed with 1% glutaraldehyde in PBS buffer for 3 min and washed over 5 min in deionized water. The sections were then treated with HQ silver enhancement solution (Nanoprobes) for 4 min and counterstained with 1% uranyl acetate for 5 min. The sections were viewed with a Zeiss Libra 120 transmission electron microscope at 120 kV.

**Chemical and enzymatic treatment**

For deacetylation, samples were chemically deacetylated through pre-treatment with 5 M NaOH at 99°C for 1 h and extensively washed with water before labelling. For re-acetylation, samples were incubated with pyridine as a base catalyst for 20 min. The same amount of acetic anhydride was then added, and the mixture was incubated for 30 min. The samples were washed twice with 0.1 M sodium methoxide in methanol to remove O-acetyl groups while preserving N-acetyl groups, and the sample was then washed with water four times before staining. For chitosanase treatment, samples were incubated in 0.03 U/ml of chitosanase (Sigma) in 50 mM sodium acetate buffer (pH 5.0) overnight at 37°C. For polygalacturonase treatment, samples were incubated in endo-polygalacturonase (Megazyme) 2.5 U/ml in 100 mM sodium acetate buffer (pH 4.2) for 3 h at 37°C.

**Labelling of samples using fluorophore-conjugated COS and OGA**

In all cases, COS and OGA were applied diluted 1 in 1000 in 50 mM MES pH 5.7. After 15 min, the samples were washed several times with MES buffer and mounted in MES buffer and glycerol solution (1:1) before viewing. Stem sections (100 μm thick) of Arabidopsis and tobacco were prepared using vibrating microtome (Vibratome, Leica VT1000S). Prior to sectioning, samples were embedded in 8% agarose gel. For COS and OGA labelling of algal materials, algae were washed three times in WH containing 9 mg/ml of MES, and the pH was adjusted to 5.7 with MES. The algae were then labelled in the dark at room temperature as described above. Where antibodies were used in conjunction with COS probes, resin sectioning and immunocytochemistry was performed as described previously (Sørensen et al., 2011). Algae were viewed with either an Olympus Fluoview 300 or
1200 confocal laser microscope. All other materials were viewed using a Leica SP-5 confocal laser microscope. The signal intensities were quantified by using ImageJ software.

Competing interests
The authors declare no competing financial interests.

Author contributions
J.M. developed the probes; S.K.K. synthesized the probes; M.G.R. performed binding data on carbohydrate arrays; B.W. F.M. and F.G.M. performed analytical and physiological experiments; P.V.C., H.H., H.D.F.L. and J.U.F. provided material and support; D.S.D. performed algal experiments; M.D. and M.H.C. performed the molecular modelling; W.G.T.W. designed the study and wrote the manuscript.

Funding
This work was supported by the FP7 Marie Curie action project CellWalDyn under contract 328830 and Danish National Advanced Technology Foundation project B21st (J.M.); by the Danish Foundation for Strategic Research (S.K.K., M.H.C. and M.D.); by the Norwegian Research Council [214613]; by the FP7 project Waste2Go B21st (J.M.); by the Danish Foundation for Strategic Research [1630]; by the Danish Foundation for Strategic Research and NSF Division of Biological Sciences [0937112]; by the US National Science Foundation (NSF) under contract 308363 (B.W.); and by the US National Science Foundation (NSF) M.D.); by the Norwegian Research Council [214613]; by the FP7 project Waste2Go B21st (J.M.); by the Danish Foundation for Strategic Research and NSF Division of Biological Infrastructure [0922825] (D.S.D.).
