SUMMARY

During oocyte maturation, capacity and sensitivity of Ca\textsuperscript{2+} signaling machinery increases dramatically, preparing the metaphase II (MII)-arrested egg for fertilization. Upon sperm-egg fusion, Ca\textsuperscript{2+} release from IP\textsubscript{3}-sensitive endoplasmic reticulum stores results in cytoplasmic Ca\textsuperscript{2+} oscillations that drive egg activation and initiate early embryo development. Premature Ca\textsuperscript{2+} release can cause parthenogenetic activation prior to fertilization; thus, preventing inappropriate Ca\textsuperscript{2+} signaling is critical to ensuring robust MII arrest. Here, we show that regulator of G-protein signaling 2 (RGS2) suppresses Ca\textsuperscript{2+} release in MII eggs. Rgs2 mRNA was recruited for translation during oocyte maturation, resulting in ~20-fold more RGS2 protein in MII eggs compared to fully grown immature oocytes. Rgs2-siRNA-injected oocytes matured to MII; however, they had increased sensitivity to low pH and acetylcholine (ACh), which caused inappropriate Ca\textsuperscript{2+} release and premature egg activation. When matured in vitro, RGS2-depleted eggs underwent spontaneous Ca\textsuperscript{2+} increases sufficient to cause premature zona pellucida conversion. Rgs2\textsuperscript{-/-} females had reduced litter sizes and their eggs had increased sensitivity to low pH and ACh. Rgs2\textsuperscript{-/-} eggs also underwent premature zona pellucida conversion in vivo. These findings indicate that RGS2 functions as a brake to suppress premature Ca\textsuperscript{2+} release in eggs that are poised on the brink of development.
INTRODUCTION

Fully grown mammalian oocytes are arrested in meiotic prophase until a mid-cycle release of luteinizing hormone from the pituitary stimulates resumption of meiosis to the metaphase II (MII) stage, referred to herein as eggs. Fusion of the egg and sperm at fertilization introduces into the egg cytoplasm a sperm-specific phospholipase (PLC\(\zeta\))(Kashir et al., 2014), which initiates IP\(_3\)-mediated Ca\(^{2+}\) release from intracellular stores. An initial prolonged rise in cytoplasmic Ca\(^{2+}\) is followed by several hours of repetitive, low frequency Ca\(^{2+}\) oscillations (Runft et al., 2002). These Ca\(^{2+}\) oscillations drive the conversion of the egg to an early embryo by causing a series of downstream responses including resumption of meiosis, cortical granule exocytosis, which prevents polyspermy, and recruitment of maternal mRNAs needed for successful embryonic development (Ducibella and Fissore, 2008).

During meiotic maturation, oocytes undergo several cytoplasmic changes that dramatically increase the ability of mature eggs to release Ca\(^{2+}\) in response to sperm or exogenous signals (Fujiwara et al., 1993; Jones et al., 1995; Mehlmann and Kline, 1994). These changes include an approximately 4-fold increase in Ca\(^{2+}\) stores (Tombes et al., 1992), an increase in inositol 1,4,5-trisphosphate (IP\(_3\)) receptor protein levels by 1.5-2-fold (Fissore et al., 1999; Mehlmann et al., 1996), and reorganization of the endoplasmic reticulum (ER) toward the plasma membrane (FitzHarris et al., 2007; Mehlmann et al., 1995), which places the Ca\(^{2+}\) stores proximal to exogenous signals. Priming of the egg for Ca\(^{2+}\) release, although needed for proper Ca\(^{2+}\) signaling after fertilization, is also associated with the risk of parthenogenetic activation should Ca\(^{2+}\) signals occur prior to sperm-egg fusion. Indeed, activation of overexpressed G\(_{q}\)-protein coupled muscarinic receptors in mouse eggs by exogenous ligands in the absence of sperm causes IP\(_3\)-mediated Ca\(^{2+}\) release, Ca\(^{2+}\) oscillations, and parthenogenetic egg activation (Moore et al., 1993; Williams et al., 1998; Williams et al.,
1992). Ca$^{2+}$ signaling prevents subsequent fertilization by inducing cortical granule release, which modifies the zona pellucida (ZP), a proteoglycan-rich extracellular matrix that surrounds the egg, to cause the “block to polyspermy.”

Because the mature egg is exceedingly sensitive to stimuli that can activate IP$_3$-mediated Ca$^{2+}$ release via G protein-coupled receptors, we reasoned that a mechanism was in place to suppress this response prior to sperm-egg fusion. Regulator of G-protein signaling (RGS) proteins are a ubiquitous family of proteins that downregulate G protein-coupled receptor signaling by inhibiting the activity of G-proteins (Heximer and Blumer, 2007). In general, RGS proteins stimulate the hydrolysis of GTP bound to activated G$\alpha$ subunits, leading to signal termination (Willars, 2006). Here we tested the hypothesis that RGS2, which inhibits both G$_q$ and G$_s$ signaling (Ingi et al., 1998; Roy et al., 2006; Wang et al., 2004), suppresses Ca$^{2+}$ release in mature mouse eggs. We report that RGS2 translation during meiotic maturation serves as a safety mechanism to prevent parthenogenetic egg activation prior to fertilization.
RESULTS AND DISCUSSION

*RGS2 protein increases during oocyte maturation.*

To determine which RGS proteins are expressed in mouse oocytes, we searched an oocyte gene expression database (Evsikov et al., 2006). Among RGS isoforms, RGS2 had the highest expression levels, ~500 transcripts per million (Blake et al., 2014). *Rgs2* mRNA was highly expressed in germinal vesicle (GV)-stage oocytes, decreased during oocyte maturation, and was greatly reduced at the 2-cell stage (Fig. 1A). In contrast, RGS2 protein was minimally detected in GV oocytes but increased about 20-fold during maturation to the MII stage (Fig. 1B,C). These findings indicate that RGS2 is developmentally regulated and suggest that it functions during oocyte maturation or beyond.

*Exposure to acidic pH causes spontaneous activation in eggs lacking RGS2.*

To test functional roles of RGS2, we used both overexpression and knockdown approaches. Because G\(_s\) activity is critical for the maintenance of prophase arrest prior to oocyte maturation (Mehlmann et al., 2002; Mehlmann et al., 2004), and RGS2 can inhibit the activity of G\(_s\) (Roy et al., 2006; Roy et al., 2003; Sinnarajah et al., 2001), we first tested whether altering RGS2 levels affected maturation success. Overexpressing RGS2 in GV oocytes did not stimulate meiotic resumption and depleting RGS2 in oocytes using RNA interference did not affect the progression of meiosis or meiotic spindle formation (Fig. 2A,B; see supplementary material Fig. S1). These results suggest that RGS2 is not required during oocyte maturation and that these approaches could be used to examine its function in MII eggs.

RGS2 potently suppresses G\(_q\) signaling (Ingi et al., 1998; Wang et al., 2004), and in mouse eggs, activation of G\(_q\) in the absence of sperm leads to Ca\(^{2+}\)-mediated resumption of meiosis.
and complete egg activation (Moore et al., 1993; Williams et al., 1998). Sperm do not appear
to utilize this pathway (Williams et al., 1998), but instead stimulate IP₃ generation directly by
introducing PLCζ {Saunders, 2002 #97; Knott, 2005 #98}. However, Gq activation triggers
the same downstream IP₃ receptor-mediated Ca²⁺ release that is essential for fertilization. To
determine whether RGS2 activity could impact Ca²⁺ signals at fertilization, we tested the
effect of RGS2-depletion on Ca²⁺ oscillatory patterns during in vitro fertilization (IVF). We
found that RGS2-depleted eggs exhibited normal Ca²⁺ oscillations, with the exception that
the duration of the first Ca²⁺ transient was slightly but consistently shorter (see
supplementary material Fig. S2A-D). This finding suggests that the Ca²⁺ stores were depleted
prior to fertilization, which could be explained by either impaired Ca²⁺ store accumulation
during maturation or by premature Ca²⁺ release. To distinguish between these possibilities,
we analyzed Ca²⁺ stores in control and RGS2-depleted MII eggs by measuring thapsigargin-
mediated ER Ca²⁺ release. There was no difference in Ca²⁺ stores between control and RGS2-
depleted MII eggs when the ZPs were intact (see supplementary material Fig. S2E-G).

As is typical for IVF experiments, the ZP was removed prior to insemination to promote
rapid synchronous fertilization during Ca²⁺ imaging. We noticed that many ZP-free, RGS2-
depleted eggs began emitting second polar bodies before sperm addition (Fig. 2C), indicating
spontaneous activation. Spontaneous activation was only observed in ZP-free RGS2-depleted
eggs, not in ZP-intact eggs (see supplementary material Fig. S3A). Our standard protocol for
ZP removal is a brief treatment with acid Tyrode’s medium. We therefore tested whether
absence of the ZP or the acid exposure was causing the spontaneous activation by using
pronase treatment as an alternative method for ZP removal. Pronase-treated eggs did not
activate, whereas eggs exposed to acid had high rates of second polar body emission and
most of the activated eggs went on to form pronuclei or to cleave (Fig. 2D, see supplementary
material Fig. S3A-D). These findings are consistent with previous observations of acid
induction of parthenogenetic activation in mouse and human eggs (Johnson et al., 1990). In addition, spontaneous Ca\(^{2+}\) changes were observed in 25% (4/16) of the siRNA-injected cells prior to addition of sperm, but never (0/15) in controls (see supplementary material Fig. S3E). These Ca\(^{2+}\) changes could explain the shortened first transients of eggs lacking RGS2 because premature Ca\(^{2+}\) release would result in Ca\(^{2+}\) store depletion prior to fertilization. To test this idea, we analyzed Ca\(^{2+}\) stores in ZP-free control and RGS2-depleted MII eggs. Ca\(^{2+}\) stores were significantly lower in RGS2-depleted eggs when the ZPs were removed using acid Tyrode’s, but no different when the ZPs were removed by manual microdissection (see supplementary material Fig. S3F-H). Taken together, these findings indicate that lack of RGS2 during oocyte maturation does not affect Ca\(^{2+}\) accumulation into ER stores, and suggest that acid-induced premature Ca\(^{2+}\) release in RGS2-depleted eggs causes a reduction in Ca\(^{2+}\) stores and, as a consequence, shortened first Ca\(^{2+}\) transients following fertilization.

*Acidic pH induces a rise in intracellular Ca\(^{2+}\) in eggs lacking RGS2 but not in control eggs.*

To characterize the acid sensitivity of RGS2-depleted eggs, we examined the effect of gradually lowering pH on Ca\(^{2+}\) release. The majority of control eggs treated with acid did not exhibit increases in Ca\(^{2+}\) even at pH as low as 5 (Fig. 2E,F). However, most RGS2-depleted eggs showed marked increases in Ca\(^{2+}\) starting between pH 6.2-6.9, suggesting that RGS2 inhibits acid-induced Ca\(^{2+}\) release. Similar results were obtained using an *Rgs2*-targeted morpholino oligonucleotide (Fig. 2G), indicating that this response was not due to a non-specific effect of siRNA.

We also examined the Ca\(^{2+}\) response to increased acid in GV-stage oocytes, which have little RGS2 protein, and throughout oocyte maturation. We found that GV- and GVBD-stage oocytes (maturing oocytes that have undergone nuclear envelope breakdown) were very sensitive to lower pH, with virtually all oocytes displaying Ca\(^{2+}\) release starting at pH 6.4-6.6.
Acid sensitivity decreased during maturation such that fewer metaphase I oocytes and MII-stage eggs responded to lower pH with Ca\(^{2+}\) release (Fig. 3A,B). This decrease in sensitivity during maturation correlated with increased translation of Rgs2. To directly examine the role of RGS2 in inhibiting acid-induced Ca\(^{2+}\) release, we overexpressed RGS2 protein in GV-stage oocytes and tested their response to acid treatment. Control oocytes released Ca\(^{2+}\) in response to lowering pH beginning at pH 6.4-6.6. In contrast, RGS2-overexpressing oocytes had a greatly reduced Ca\(^{2+}\) response, with fewer cells responding and the total Ca\(^{2+}\) released much lower when Ca\(^{2+}\) release occurred at all (Fig. 3C,D).

In somatic cells, RGS2 inhibits acid-induced responses, such as those induced by alterations in pH that result from inflammatory conditions including asthma (Liu et al., 2013). Studies in airway epithelial cells suggest that lower pH activates the G\(_q\)-coupled proton sensor, GPR68 (also called OGR1), to release Ca\(^{2+}\), which stimulates the production of MUC5AC (Liu et al., 2013; Ludwig et al., 2003; Saxena et al., 2012). RGS2 overexpression prevents acid-induced secretion of MUC5AC, and RGS2 depletion increases this response (Liu et al., 2013). These results indicate that RGS2 acts as an inhibitory regulator of acid-induced cellular responses by binding to G\(_q\). GPR68 or a similar receptor could act as a proton sensor linked to Ca\(^{2+}\) signaling by activating G\(_q\) in oocytes. Indeed, GV-stage oocytes have significant levels of Gpr68 transcripts compared to that in MII eggs and early embryos (Fig. 3E). It is unclear if mouse eggs are exposed to low pH under physiological conditions within the ovarian follicle or oviduct, as direct measurements have not been reported. In larger species, follicular fluid and oviduct pH is generally in the range of 7-8 (reviewed in (Edwards, 1974; Stone and Hamner, 1975)), but pH has been measured as low as 6.8 in bovine follicles and pig oviducts (Smiljaković et al., 2008; Zachariae and Jensen, 1958). In addition, follicle or oviductal pH could drop during an inflammatory process as has been observed in inflamed airways (Liu et al., 2013).
Acetylcholine causes Ca\textsuperscript{2+} release in oocytes and RGS2-depleted eggs.

In addition to an acidic environment, eggs could be exposed to other stimuli that activate G\textsubscript{q} in vivo. One such stimulus is acetylcholine (ACh). Choline acetyltransferase, which synthesizes ACh, is expressed in granulosa cells from large antral follicles of human, monkey, and rat ovaries (Fritz et al., 1999; Fritz et al., 2001; Mayerhofer et al., 2006). Moreover, ACh has been measured in cultured human and rat granulosa cells (Fritz et al., 2001) and in adult rat ovaries (Mayerhofer et al., 2006). Interestingly, the amount of ACh in rat granulosa cells is significantly increased by follicle stimulating hormone (Mayerhofer et al., 2006), suggesting that maturing oocytes are exposed to ACh in vivo. ACh treatment stimulates Ca\textsuperscript{2+} release via G\textsubscript{q}-coupled muscarinic receptors, which are expressed in oocytes of several species including mouse (Caratsch et al., 1984; Eusebi et al., 1979; Eusebi et al., 1984). In addition, stimulation of the muscarinic receptor induces Ca\textsuperscript{2+} release in immature growing mouse oocytes (Carroll et al., 1994) but not in MII eggs (Williams et al., 1998).

We examined the ability of ACh to stimulate Ca\textsuperscript{2+} release in oocytes, eggs, and RGS2-depleted eggs. All of the GV-stage oocytes and RGS2-depleted eggs released Ca\textsuperscript{2+} in response to addition of ACh, whereas the majority of control eggs that contained RGS2 showed no response (Fig. 4A,B). Treatment of GV-stage oocytes with the muscarinic receptor antagonist atropine almost completely suppressed ACh-induced Ca\textsuperscript{2+} release (Fig. 4C), but did not affect acid-induced Ca\textsuperscript{2+} release (data not shown). These findings indicate that RGS2 effectively inhibits G\textsubscript{q}-mediated Ca\textsuperscript{2+} release in response to ACh, and suggest that one function of the maturation-associated accumulation of RGS2 protein is to suppress this physiological response.
**RGS2-depleted eggs undergo premature ZP conversion**

Ca\(^{2+}\) release at fertilization triggers cortical granule exocytosis and release of the protease ovastacin, which cleaves the ZP protein ZP2 to ZP2\(_f\) (Burkart et al., 2012). This cleavage event is responsible for the ZP block to polyspermy. Because cortical granule release in eggs is easily triggered in response to rises in cytoplasmic Ca\(^{2+}\) (Ducibella et al., 2002), ZP2 cleavage can be used as a proxy for Ca\(^{2+}\) release over time. To test whether RGS2 regulates Ca\(^{2+}\) release during oocyte maturation, we microinjected GV-stage oocytes with Rgs2 siRNA, matured them, and then measured the percentage of ZP2 to ZP2\(_f\) conversion. RGS2-depleted eggs consistently had elevated levels of ZP2 conversion compared to controls (Fig. 4D,E). These findings demonstrate that during *in vitro* maturation of RGS2-depleted oocytes, Ca\(^{2+}\) increases occurred that were sufficient to cause cortical granule release and promote ZP2 conversion.

A full knockout RGS2 mouse has been developed and this mouse has at least two defects due to inappropriate Ca\(^{2+}\) regulation. RGS2 knockout pancreatic acinar cells have significantly higher IP\(_3\)-mediated Ca\(^{2+}\) release in response to muscarinic receptor activation (Wang et al., 2004). In addition, these knockout mice have high blood pressure due to increased Ca\(^{2+}\) release in response to vasoconstrictors, which act through Gq-coupled receptors. To determine if loss of RGS2 *in vivo* resulted in abnormal responses to G protein-coupled receptor agonists, we tested the effects of ACh and acidic pH on MII eggs from *Rgs2\(^{+/+}\)* and *Rgs2\(^{-/-}\)* females. Consistent with our findings in RGS2-depleted eggs, 100% of the *Rgs2\(^{-/-}\)* eggs responded to ACh by releasing Ca\(^{2+}\) (Fig. 4F). Only 12/26 *Rgs2\(^{+/+}\)* eggs showed some degree of response to ACh, but far less Ca\(^{2+}\) was released than in *Rgs2\(^{-/-}\)* eggs (Fig. 4G). Similarly, *Rgs2\(^{-/-}\)* eggs responded at a higher pH and released more Ca\(^{2+}\) than *Rgs2\(^{+/+}\)* eggs (Fig. 4H,I). Of note, control eggs in these experiments, which were from C57BL/6J females, were more sensitive to both ACh and acid when compared with the CF-1...
eggs used in previous experiments, as demonstrated by the greater proportion showing responses. These findings draw attention to mouse strain differences that likely underlie conflicting reports regarding responses of MII eggs to ACh (Kang et al., 2003; McGuinness et al., 1996; Williams et al., 1992). In fact, the MF-1 mouse strain, which produces eggs that have a high incidence of activation following acid-mediated ZP removal (Johnson et al., 1990), was the subject of a quantitative trait locus analysis that identified the Rgs2 gene locus as a modulator of anxiety (Yalcin et al., 2004). These findings suggest that differences in RGS2 expression or function contribute to the increased sensitivity of MF-1 eggs to ACh and acid activation.

RGS2 knockout mice are viable and fertile, but no formal breeding study has been reported. We analyzed litter sizes from ongoing production of Rgs2+/+ and Rgs2−/− mice over a 32-month period. The average litter size of Rgs2−/− females was significantly lower than that of Rgs2+/+ females (Fig. 4J). This finding was due to subfertility of the Rgs2−/− females because litters of Rgs2+/+ females mated to Rgs2−/− males were not smaller than those of wild type pairs (data not shown). A possible explanation for the reduced litter size was premature cleavage of ZP2 similar to that observed in RGS2-depleted eggs, which could result in impaired fertilization. To test this idea, we collected MII eggs from Rgs2+/+ and Rgs2−/− females 16 hours after hCG administration and quantified ZP2 conversion to ZP2f. Indeed, Rgs2−/− eggs had obviously increased levels of ZP2 conversion compared to those from Rgs2+/+ females (Fig. 4K,L). These findings indicate that RGS2 suppresses Ca2+ release in vivo. The finding that the mice were not completely infertile suggests that, in addition to RGS2, other mechanisms may be in place to help prevent premature Ca2+ release.

In conclusion, a dramatic rise in intracellular Ca2+ is of paramount importance for successful egg activation and embryo development in all animals (Kashir et al., 2013). Mammalian oocytes do not develop the ability to efficiently release large amounts of Ca2+ until
immediately before ovulation, thereby preventing premature Ca\textsuperscript{2+} release that could preclude successful fertilization. As the oocyte becomes fertilization-competent, it is exquisitely sensitive to signals that release Ca\textsuperscript{2+} (Fig. 4M). Our findings suggest that RGS2 functions to inhibit premature G-protein mediated Ca\textsuperscript{2+} release in eggs that are poised for activation by PLC\textsubscript{ζ} from the fertilizing sperm.

MATERIALS AND METHODS

Gamete collection and oocyte microinjection
Oocytes, eggs, embryos, and sperm were collected and oocytes were microinjected with 5-10 pl volume essentially as previously described (Bernhardt et al., 2011; Jefferson et al., 2009). Pipette concentrations of microinjected reagents were as follows: Rgs2 siRNA (Ambion) and control nontargeting siRNA (Santa Cruz), 2 μM; Rgs2 and control morpholinos (GeneTools), 2 mM; and HA-RGS2 cRNA, 1 μg/μl. siRNA- and morpholino- injected oocytes were cultured in 10 μM milrinone for 5-8 hours to allow protein turnover and then matured. cRNA-injected oocytes were incubated in milrinone-containing medium for 18-20 hours prior to imaging to allow protein overexpression. For some experiments, ZPs were removed by brief exposure to acidic Tyrode’s solution, pH 1.6, by incubation for 4-8 min in 5 mg/mL pronase, or by piezoelectric actuated drilling of a 50 μm slit in the ZP followed by gentle pipetting using a 70 μm inner diameter capillary. Culture media used is detailed in supplementary Materials and Methods.

Calcium imaging
Ca\textsuperscript{2+} imaging was performed as previously described (Miao et al., 2012). For fertilization experiments, ZP-free eggs were adhered to Cell-Tak-coated dishes in BSA-free medium under mineral oil. Capacitated sperm were added to a final concentration of 10\textsuperscript{5} sperm/mL.
For acid addition and ACh experiments, ZP-intact cells were used. 1 N HCl was diluted 1:100, and 150 μL quantities of this solution were added to 2 mL medium several minutes apart during imaging. pH measurements were made using parallel additions of the dilute HCl to the same medium volume. ACh was prepared as a 5 mM stock in water and added to L-15 medium during imaging to achieve final concentrations of 2 μM, 200 μM and 1 mM.

**Immunofluorescence and immunoblotting**

For spindle staining, eggs were fixed, extracted, and blocked as previously described (Bernhardt et al., 2012). Oocytes, eggs, or embryos were lysed in sample buffer, separated under reducing conditions and immunoblotted as previously described (Jefferson et al., 2013). Details regarding antibodies are provided in supplementary Materials and Methods.

**qRT-PCR**

Total RNA was isolated from 50 oocytes, eggs, or embryos using an Arcturus Pico Pure kit (Life Technologies). EGFP cRNA was generated as previously described (Miao et al., 2012) and 10 pg was added to each sample prior to RNA isolation as an internal control. Real time RT-PCR was performed as previously described (Jefferson et al., 2013) using cDNA from 2 oocytes or embryos per reaction. Primer sequences are provided in supplementary Materials and Methods. Relative gene expression was calculated by the ΔCt method (Pfaffl, 2001) using EGFP expression for normalization.

**Statistical Analysis**

Data were analyzed using one-way ANOVA, Student’s t-test, Mann-Whitney U-test, or chi-square test, as indicated in figure legends. Statistical tests were performed using GraphPad Prism.
